In cohort studies, subjects are identified in terms of exposure or nonexposure status and are observed for a specified time to determine the presence or absence of a health outcome. Cohort studies are divided into prospective and retrospective. In prospective cohort studies, the exposure or nonexposure status is defined when the study is initiated. The subjects of investigation are followed up into the future to determine disease or nondisease status. In retrospective studies, the status of exposed or nonexposed is defined in the present. In prospective cohort studies, exposures of the present are evaluated; in retrospective cohort studies, exposures of the past are being evaluated. Cohort groups share the common exposure status and are observed to ascertain the presence or absence of a disease or outcome.

Retrospective Cohort Studies
A second retrospective design is the retrospective cohort study, in which subjects are identified from archival data collected many years previously and located in the present. In other words, exposure status is defined in the past, and illness status is defined in the present. A classic example of this type of design is a study entitled Deviant Children Grown Up (Robins 1966), in which 524 individuals who had been evaluated 30 years earlier in a child guidance clinic, along with demographically matched school-based control subjects, were assessed with respect to subsequent psychopathological processes and sociopathic behaviors. The data in the agency records served as predictor variables in the analysis. This design has the advantage of obtaining information in a timely and cost-effective manner. The primary disadvantage, however, is that the interval experiences are reconstructed for long periods and, in the absence of objective records, may be subject to considerable recall bias. Another disadvantage is that the samples themselves may not be representative of individuals with the exposure. Furthermore, some studies have reported considerable loss to follow-up through either mortality or mobility. For example, in a long-term “follow-back” study of patients from a clinic in Switzerland, Cioimi (1980) assessed only 289 of the original 1642 patients, or 18%.

Prospective Cohort Studies
In prospective cohort studies, subjects are identified in terms of exposure or nonexposure status and observed forward for
a specified interval to determine the presence or absence of a health outcome. Cohort studies are similar to an experimental study with the exception that exposure or nonexposure status is not assigned by the investigator. To illustrate, Solomon (1993) identified a sample of Israeli soldiers who fought in the war between Israel and Lebanon and soldiers who were not on active duty at the time. After the war, they were followed up for several years to determine the onset of long-term war-related mental disorders. The prevalence of subsequent psychiatric illness was significantly higher in the soldiers exposed to war than in soldiers not exposed.

The sources of cohort groups are variable. The most powerful type of cohort is the birth cohort drawn from the general population. Two British birth cohorts have been used to study a range of diseases, including schizophrenia (Crow and Done 1992). Another powerful source of a cohort is a community. In 1947, Essen-Moller began a longitudinal study of the 2550 inhabitants of Lundby, Sweden; the cohort was subsequently followed up for more than 25 years (Hagnell et al. 1982). Often, healthy cohorts are identified from specific settings, particularly universities and medical facilities. For example, a well-known study in American psychiatry is Vaillant’s (Vaillant 1983) 40-year study of initially healthy Harvard University undergraduates. Another common population targeted for cohort research is an occupational group. To minimize bias in determining whether an occupational condition is associated with an adverse health outcome, members of occupational cohorts must be identified at the point of hire. Because most disorders occur infrequently, another cohort source frequently used in psychiatry is the offspring of mentally ill adults, such as children of individuals with alcoholism, children of individuals with schizophrenia, and children of depressed parents.

For comparison groups, a cohort study can use an internal subset of the population under study, by comparing exposed with unexposed members of the cohort, or an external comparison. A comparison cohort can be selected from a similarly defined population (e.g., mothers living near Three Mile Island were compared with mothers similarly sampled from another nuclear power plant), or the cohort can be compared with the general population (e.g., symptoms among women living near Three Mile Island can be compared with norms established for the same measure for women of the same age).

The major strength of the cohort design is the possibility of estimating a temporal relationship between exposure and disease. With a cohort study, it is possible to study rare exposures and to evaluate multiple outcomes from a single exposure. The limitation of cohort studies is primarily one of feasibility because most such studies are expensive and involve study populations that are difficult to recruit and maintain for follow-up.

### Threats to Validity in Epidemiological Studies

An essential feature of epidemiological studies is a comparison of two groups in terms of presence or absence of exposure or presence or absence of disease. For the measurements to be comparable, the investigator should ensure absence of bias. Biases can be divided into three general types: selection bias, information or observation bias, and confounding bias.

### Selection Bias

Selection bias can arise when the sampling procedure is influenced a priori by the disease or the exposure. For example, studies of employed populations are limited by the “healthy worker effect” because disabled individuals or those who were adversely affected by aspects of the work environment will not be in the cohort (Monson 1980). The Three Mile Island investigation compared unionized nuclear power plant workers at Three Mile Island with workers at a comparable power plant in western Pennsylvania (Bromet et al. 1982). Because of union regulations, the workers at Three Mile Island could not transfer to a less stressful type of power plant without losing their seniority and benefits, but the comparison site employees could and did transfer. Thus, because of the bias introduced by the different union regulations, the two samples were not comparable.

Another example, referred to as self-selection bias, occurs when subjects who have been exposed to an event are more likely to participate in a study if they have the disease or prodromal stages of the disease under study. A similar type of selection bias can occur when subjects are solicited from newspaper or other similar advertisements. To illustrate, in a study of individuals who responded to an advertisement seeking healthy volunteers as control subjects in a mental health study, Halbreich et al. (Halbreich et al. 1989) reported that one-third had a history of diagnosable mental disorders. Selection bias can also occur when the mortality rate is elevated as a result of the exposure. Thus, concentration camp survivors or survivors of major earthquakes are not necessarily representative of individuals who underwent those stresses.

When an investigator suspects selection bias at the start of a study, it is usually difficult to isolate the source because it is often impossible to obtain sufficient information about the nonrespondents. As we will see later in the chapter, Kessler et al. (Kessler et al. 1994) conducted a special study of nonrespondents to the NCS and discovered that they had a higher rate of psychiatric illness than did the sample interviewed without special procedures. On the other hand, considerable detail has accumulated about individuals who drop out of longitudinal studies. Such individuals tend to be at both ends of the spectrum, that is, they have either the highest or the lowest degree of psychiatric illness. Each longitudinal study needs to include an analysis of the bias imposed by attrition.

### Information (Observation) Bias

In case-control studies, information bias occurs when the details about prior exposure are obtained in a noncomparable manner or are subject to poor recall. To minimize such bias in case-control studies, exposure data should be collected without knowledge of disease status. This procedure is known as blindness. However, because of selective recall, when the sole source of information is the affected individual, this type of bias sometimes presents insurmountable problems (see also Chapter 27) for a discussion of this phenomenon). For instance, in studies of life events and onset of depression, it is likely that subjects who present with the disease under study will have a more accurate recollection of life events than will individuals without depression. Subjects themselves may break the blind feature built into a study. In research on occupational lead exposure, an
attempt was made to keep the interviewers blind as to exposure status by putting all questions about employment at the end of the interview (Parkinson et al. 1986). However, the subjects frequently volunteered information about their jobs early in the interview. Another example comes from clinical trials in which raters can, sometimes, accurately guess which subjects are receiving placebo and which are not and, hence, bias the results about the drug’s effects.

**Confounding Bias**
Confounding bias results when a third factor that is a cause of the disease under study is also associated with the exposure. A confounding factor is a cause of the disease under study independent of its association with the exposure. For instance, if unemployment is considered a cause of suicidal behavior, and, at the same time, alcoholism is related to both unemployment and suicidal behavior, then alcoholism would be a confounding variable for a study designed to measure the association between unemployment and suicidal behavior. In such a study, the measure of association between unemployment and suicidal behavior should be adjusted by the presence or absence of alcoholism.

**Examples of Psychiatric Epidemiological Studies**
Dohrenwend and Dohrenwend (1982) have divided the growth of psychiatric epidemiological research into three periods, or generations. This section describes the key studies and prevalence rates from each of these periods.

**First-Generation Research**
The first-generation studies took place for the most part before World War II. These studies are characterized by their reliance on known cases, usually individuals in mental hospitals, to define mental illness. There were three extraordinary studies conducted during this time. The first was a prevalence study performed in 1885 in Massachusetts in which case patients were identified through key informants, such as general practitioners and clergy, and hospital records (Jarvis 1971). This study, the first known American prevalence study, identified 2632 “lunatics” and 1087 “idiots” in need of care.

The second landmark study in the history of psychiatric epidemiology was an etiological study of pellagra, a common disorder found in patients in mental hospitals. In the early 1920s, Goldberger et al. (Terris 1964) demonstrated with the case-control method that pellagra was associated with nutritional deficiency. Although no specific nutrient was identified, dietary changes were instituted that dramatically reduced the level of morbidity from this disease in institutional settings.

The third landmark study conducted before World War II was an ecological analysis of hospital patients, *Mental Disorders in Urban Areas* (Faris and Dunham 1939). This pioneering study examined the geographical distribution of all first-admission patients hospitalized between 1922 and 1934 in mental hospitals in Chicago. They found that the central area of the city, which had the greatest degree of social disorganization, had the highest rates of admissions for patients with schizophrenia (46% of all admissions). The rates decreased progressively with distance away from the center, reaching a low of 13% in the outermost area. This study became influential in mental health research because the investigators interpreted the results as indicating that adversity in the social environment played an etiological role in the occurrence of severe mental illness. Critics argued that downward social drift could have accounted for the high number of cases from the central urban area. Because the study used an ecological design, the data could not be used to test causal hypotheses about the relative role of personal versus environmental risk factors. Nevertheless, the debate about the causal contributions of these risk factors led to an extensive body of research on the contribution of social factors to the onset of mental illness.

In general, the median prevalence rate among the various first-generation studies relying on key informants and agency records was 3.6% (Dohrenwend and Dohrenwend 1982). Compared with findings from later studies, this design is generally believed to result in an underestimate of the true prevalence of mental disorders.

**Second-Generation Studies**
World War II represented a turning point in psychiatric epidemiology (Weissman and Klerman 1978, Dohrenwend and Dohrenwend 1982). A number of events converged during this time. First, mental illness accounted for the largest proportion of men rejected for military service. The fact that such large numbers of (untreated) recruits failed the psychological screen emphasized that treated patients, who served as the foundation of previous prevalence estimates, represented the tip of the iceberg, albeit a biased one. Second, healthy men who fought in the war frequently suffered from combat stress reactions when faced with the overwhelming horrors of battle, indicating that stress can play an etiological role in the onset of mental disorders under some circumstances. Some of these individuals were subsequently discharged because of psychiatric illness (Grinker and Spiegel 1945). Also, psychologists in the armed forces developed the Neuropsychiatric Screening Adjunct, which became a forerunner of symptom questionnaires administered after the war.

In 1946, the Congress passed the National Mental Health Act (Public Law 79-487), enabling the creation in 1949 of the NIMH as a separate agency within the National Institutes of Health. This facilitated governmental support of training, prevention, and epidemiological research in mental health. The second-generation studies profited from this financial support. Growing conceptually out of the experiences of World War II that suggested a major role for stress in relation to mental disorders, these studies focused on early childhood and contemporaneous sources of stress believed to influence psychological well-being adversely.

In the early 1950s, three major studies were initiated to examine the prevalence of and risk factors associated with psychosomatic and affective symptoms in the general population, the Midtown Manhattan Study (Srole et al. 1962), the Nova Scotia Stirling County research (Leighton et al. 1963), and the University of Michigan’s national survey of mental health (Gurin et al. 1960). These early representatives of the second-generation studies used lengthy symptom questionnaires, modified in large part from the Neuropsychiatric Screening Adjunct, which were directly administered to carefully selected samples of the population. The underlying assumption of these studies was that
mental illness existed along a unidimensional continuum of severity, and that impairment ratings by psychiatrists who reviewed the symptom questionnaires were appropriate and suitable reflections of true mental illness. This conceptualization of mental illness as existing along a continuum was congruent with the paradigm of social disruption as an etiological factor of psychiatric illness.

The common denominator of the early second-generation studies was the direct interview of all subjects with supplementation of data from other sources, such as medical or community records. The care and elegance of the data collection in the earlier studies are important to emphasize. For example, in the Stirling County study, 1010 adults were assessed initially by a lay interviewer using a structured questionnaire (Leighton et al. 1963). Further information was collected from general practitioners and psychiatrists practicing in the area. All of the information was evaluated by research psychiatrists using the DSM-I nosology. The prevalence of mental illness was estimated to be 20%. The Midtown Manhattan Study (Srole et al. 1962) used a similar methodology; social workers were hired to collect the interview data. On the basis of psychiatrists’ ratings of impairment, this study reported that 23.4% of the sample was severely impaired.

In the late 1950s, Hollingshead and Redlich (Hollingshead and Redlich 1958) conducted a landmark study of the impact of social class on the treatment experiences of psychiatric patients, drawing on treated patients from the city of New Haven, Connecticut. Similar to the Chicago study of Faris and Dunham (Faris and Dunham 1939), major differences were found across socioeconomic strata. The most influential finding was that regardless of diagnosis, the type of therapy patients received varied according to their class of origin. Patients from the working and lower classes were more likely to be treated with electroconvulsive therapy or medications. In contrast, patients from the upper classes were mostly treated with psychotherapy. Researchers also found a higher treated prevalence for the lower social classes.

Later second-generation studies used abbreviated assessment methods empirically derived from the lengthy symptom inventories and eliminated the role of psychiatrists in case identification. These studies continued to focus on the role of social adversity in the occurrence of psychiatric symptoms. However, these studies have been criticized for not adequately assessing the full range of psychiatric symptoms, particularly those associated with psychosis, aggression, and substance use, and, hence, drawing biased conclusions about both rates and risk factors (such as female gender). Furthermore, although many such studies were longitudinal (e.g., the New Haven study of stressful life events and symptoms) (Myers et al. 1971), they were unable to disentangle cause and effect because they were not prospective (i.e., they did not start with a healthy cohort and detect whether or under what conditions the risk factors observed led to new cases of individuals with high symptom counts). The primary limitation, however, was the assessment of symptoms rather than diagnosable-level disorder.

Nevertheless, it became clear that mental illness was a public health problem and that most individuals with significant symptoms never received psychiatric treatment. In part on the basis of these community studies, including the highly influential Social Class and Mental Illness, President Kennedy delivered a message to the Congress on mental illness and mental retardation in 1963 that set the stage for the Community Mental Health Centers Act.

**Third-Generation Studies**

The methodology for the third-generation epidemiological studies reflected the view in American psychiatry in the early 1970s that mental illness could be delineated into discrete, operational categories. These changes in nosology were exemplified in the 1970s with the development of the Feighner criteria at Washington University in St. Louis (Robins and Guze 1970, Feighner et al. 1972) and culminated in the creation of DSM-III a decade later. By operationalizing diagnoses with specific criteria, it was possible to create structured diagnostic assessments to elicit the symptoms needed for these categories. Preliminary evidence about the utility of using diagnostic procedures in community samples was obtained in a third-wave follow-up of the New Haven study noted before. In this study, Weissman et al. (Weissman et al. 1978) successfully administered the SADS-L in a community population. This and other studies (Bromet et al. 1982) demonstrated that structured diagnostic instruments designed for clinical investigations could produce meaningful findings when administered in population-based studies.

The third-generation studies, thus, are characterized primarily by the use of structured diagnostic assessment procedures. In the next sections, we describe the largest third-generation studies, the ECA, the NCS, and NCS-R. Many other important investigations focusing on diagnosable mental disorders have also been conducted. These include (but are not limited to) the National Vietnam Veterans Readjustment Study (Kulka et al. 1990), the prevalence study of major depressive disorder and alcohol abuse or dependence in white-collar employees of Westinghouse Electric Corporation (Bromet et al. 1990), the prevalence and risk factor study of psychiatric disorders in an Israeli birth cohort (Dohrenwend et al. 1992, Levav et al. 1993), the social risk factor study of adults residing in metropolitan Toronto (Turner and Mariano 1994), and the MacArthur Foundation’s Midlife Development in the United States (MIDUS) survey (Wang et al. 2000). It is also important to note the progress in studying the epidemiology of children’s disorders. Since Rutter’s (Rutter et al. 1976) pioneering research of children living on the Isle of Wight and in an inner-city area of London, several community studies have been conducted using structured diagnostic assessment procedures. These studies have been conducted in several countries, including Canada (Ontario) (Offord et al. 1987), United States (New York State (Velez et al. 1989), Pittsburgh (Costello et al. 1988), Puerto Rico (Bird et al. 1988), New Zealand (Anderson et al. 1989), and France (Fombonne 1994). In a review of prevalence studies, Costello (1989) concluded that the rate of diagnosable mental disorders in children and adolescents may be as high as 18–20%.

**The Epidemiological Catchment Area Study**

In response to the 1978 President’s Commission on Mental Health report, NIMH sponsored the ECA project to determine the prevalence of mental disorders in specific sites and the proportion receiving mental health services (Regier et al. 1984). Parallel to the planning of the ECA study, the American Psychiatric Association published the DSM-III
(American Psychiatric Association 1980), which had clearly defined, operational criteria that facilitated case definition. Thus, the concept of a case as a discrete entity that had been achieved in the late 1970s permitted the categorical determination of psychiatric caseness as opposed to the dimensional assessment of symptom impairment. As a prelude to the ECA, the NIMH cosponsored the development of the DIS (reviewed earlier).

**Design**

The ECA study estimated the prevalence of mental disorders in designated catchment areas with at least 200,000 persons. Catchment areas were selected within New Haven, Connecticut; Baltimore, Maryland; Raleigh-Durham, North Carolina; St. Louis, Missouri; and Los Angeles, California. In each location, approximately 3000 individuals were assessed initially (Regier and Kaelber 1995). The sampling was not intended to provide national estimates; rather, the focus on specific geographical sites facilitated the project’s goal of linking mental health assessments to service use information.

The basic design involved face-to-face baseline interviews with random samples of adults selected from the catchment areas, 6-month telephone follow-up interviews to obtain interim information on medical and psychiatric service use, and 1-year face-to-face interviews with the original sample. The initial response rate ranged from 68% (Los Angeles) to 79% (St. Louis and Durham) (Leaf et al. 1991). Overall, 12% of the original respondents were lost to follow-up assessments of healthy individuals found during the initial assessments (Regier et al. 1993). Because some ECA respondents reported symptoms inconsistently across the two waves of interviews, Eaton et al. (Eaton et al. 1989) reported that failure to be tracked was associated with being male, young, unmarried, and Hispanic; refusal to participate was associated with being older, married, and uneducated.

**Prevalence**

Overall, 32.2% of the adults included in the five sites met criteria for one or more of the assessed mental disorders during their lifetime (Table 25–1 and Figure 25–2). Phobias and alcohol abuse and dependence were the most common mental disorders (Regier et al. 1988). The lifetime prevalence for phobia was 12.5%, and the 1-month prevalence was 6.2% (Tables 25–1 and 25–2). The rates for drug abuse and dependence were 5.9% for lifetime and 1.3% for 1-month prevalence (Tables 25–1 and 25–2).

The ECA study investigators did extensive analyses of the variation in prevalence rates by demographic characteristics. For lifetime diagnosis, 36% of men at some point suffered from an addictive or mental disorder, compared with 30% of women (Table 25–3 and Figure 25–3). As seen in Table 25–3, some differences also emerged by age groups, with age groups younger than 30 and 30–44 years having the highest lifetime prevalence rates. Interestingly, individuals older than 65 years reported lower prevalence rates, suggesting a possible underreporting of symptoms in this age group (Robins et al. 1991). Furthermore, Regier and Kaelber (1995) suggested that it is possible that individuals with psychiatric disorders tend disproportionately to die prematurely. Table 25–3 also indicates that the rates overall are higher in African-Americans than in Whites and Hispanics, but this is confounded by social strata because rates are similar across ethnic groups when social class is controlled (Regier and Kaelber 1995). Similarly, individuals who did not complete high school had a higher prevalence of mental disorders than did those who graduated from high school (see Table 25–3). Lifetime prevalence rates were also associated with unemployment (especially in men) and with being separated or divorced (see Table 25–3). The pooled 1-month prevalence rates for the five sites (see Table 25–2) was 15.4% for all ages for any DSM-III disorder. The age group 25–44 years had the highest overall rate of 17.3%. Although this age pattern was also true for women, men aged 18–24 years had the highest overall rate. This occurred because of the peak in rates of drug abuse and dependence in men in this age group. Anxiety disorders were most prevalent at 11.7% in women 25–44 years old, compared with only 4.7% for men in the same group. The overall prevalence for all affective disorders was 5.1%; the age group with the highest prevalence was women 25–44 years old.

**Incidence**

Incidence rates were calculated based on the 12-month follow-up assessments of healthy individuals found during the initial assessments (Regier et al. 1993). Because some ECA respondents reported symptoms inconsistently across the two waves of interviews, Eaton et al. (Eaton et al. 1989) presented estimates adjusted for this unreliability for seven disorders (major depressive disorder, panic disorder, phobia, obsessive-compulsive disorder, drug abuse and dependence, alcohol abuse and dependence, and cognitive impairment). Overall, phobias had the highest incidence rate (4.0%);

*Based on five ECA sites.

panic disorder and obsessive-compulsive disorder had the lowest (0.6% and 0.7%, respectively). The female/male ratio for phobias was approximately 3:1. Women also had a higher rate of obsessive-compulsive disorder. The opposite was found for drug abuse and dependence, with men having a much higher 1-year incidence rate. Also, as expected, older age groups had virtually no new cases of drug abuse and dependence. Interestingly, the incidence of alcohol abuse and dependence was somewhat associated with age; a slight increase was found after the age of 60 years and even more after 75 years. For 1.6% with new onsets of major depressive disorder, women, especially those in their mid-40s, were at highest risk (female/male ratio was more than 2:1).

During the 1-year follow-up period, 6% of the total population had one or more new disorders (Regier et al.)
1993). Also, 5.7% of those with a history of a mental disorder suffered a relapse or a new condition in the 1-year period for a total of 12.3% of new cases in 1 year.

**Institutionalized Sample**

The ECA investigators interviewed individuals institutionalized in psychiatric hospitals, halfway houses, nursing homes, and prisons. Not surprisingly, rates were much higher in these institutionalized populations. Estimates of lifetime prevalence of 65% and 1-year prevalence of 51% were reported (Regier and Kaelber 1995). Also, not surprisingly, the prevalence of different diagnoses varied depending on the type of the institution (Robins et al. 1991).

**Use of Mental Health Services**

Although 28.1% of the sample had diagnosable mental or addictive disorders, only 14.7% (23 million) received care, indicating that a disproportionate number of individuals suffering from mental and addictive disorders did not receive treatment. Conversely, although 22% of respondents who had recently used a medical care facility met criteria for a DSM-III disorder, 17% of nonusers had a diagnosable illness (Kessler et al. 1987, Eaton et al. 1989, Narrow et al. 1993, Regier et al. 1993). The disorders making the greatest contribution were alcohol abuse and dependence in men and major depression in women. The ECA study found that 0.9% received inpatient treatment in a specialty mental and addictive disorders facility during a 1-year period. Among individuals with any DSM-III disorder who received mental health services, 28.5% sought treatment from either a mental health clinician or medical physician (see Table 25–4).

**Comorbidity of Mental and Substance Use Disorders**

The ECA study provided valuable data about the prevalence of comorbidity of alcohol and substance use disorders with mental disorders (Regier et al. 1988, 1990). Before the ECA study, most of the information about comorbidity came from populations in treatment settings. Since the early 1950s, it has repeatedly been found that patients in clinical settings typically present themselves for treatment because they have more than one disorder, a phenomenon first described by Berkson (1946). Thus, clinical populations provide a biased (and inflated) view of comorbidity.

The ECA study defined comorbidity as the occurrence of more than one disorder and did not require that the disorders overlap temporally. Up to 29% of individuals with a mental disorder suffer from a comorbid substance use disorder. Similarly, individuals with alcohol use disorder have twice the risk of having a comorbid mental disorder and more than five times the risk of having a comorbid drug use disorder. Of all mental disorders, antisocial personality disorder carried the highest risk of having a comorbid substance use disorder, 83.6%, which translates to nearly 30 times the odds of having a substance use disorder compared with the general population. Bipolar disorder had the next highest prevalence of substance use disorder (60.7%), and the odds of having a substance use disorder were 7.9 times higher than that of the general population. Interestingly, the rate of substance use disorder in respondents with bipolar disorder was higher than in those with major

Depressive disorder or schizophrenia. Furthermore, 26.7% of respondents with bipolar I disorder had a comorbid drug dependence disorder. The cause for such high prevalence of substance use disorder comorbidity in patients with bipolar disorder remains unclear (Tohen 1994, Tohen and Goodwin 1995). Among individuals with alcohol use disorders, the most common comorbid mental disorder was anxiety disorder, with a prevalence of 19.4%. For individuals with drug use disorder, 22% suffered from a mental disorder. Again, anxiety disorder was the most prevalent with 28.3%.

In summary, findings from the ECA confirmed the widespread and impairing nature of mental disorders reported in the second-generation community studies described earlier. The methodologic rigor with which the ECA was conducted was instrumental at dispelling the disbelief and criticism of methodology that frequently accompanied second-generation studies. The rates in the five ECA sites confirmed the high prevalence of untreated mental disorder. ECA results, such as the finding that individuals with mental disorders were relatively more likely to use general medical services compared with those without disorders, raised provocative questions for a new generation of psychiatric epidemiologists.

The National Comorbidity Survey
Because the ECA study was conducted in five specific sites, each selected because it contained unique population characteristics, the findings could not be readily extrapolated to the United States as a whole. Therefore, the NCS was designed to estimate the prevalence and comorbidity of psychiatric and substance use disorders in the mainland United States. The NCS was designed by Kessler et al. (Kessler et al. 1994) as the first population-based study administered to a nationally representative sample in the United States using a structured diagnostic interview. It built upon a history of conducting (second-generation) national studies of the prevalence of psychiatric symptoms in the United States at the University of Michigan. The NCS also built on the knowledge and experience of the ECA study. Among its many advantages, it uniformly included a set of demographic and psychosocial risk factors.

Design
The NCS used a stratified probability sampling procedure and focused on individuals aged 15–54 years. It included only noninstitutionalized individuals in 48 states. A total of 8098 individuals were interviewed, which represented 82.6% of the targeted population. To understand the full impact of nonresponse, we reapproached a random sample of the initial refusers and gave them further incentives to participate in a short form of the original interview. These individuals were subsequently found to have elevated rates of psychiatric illness. Therefore, a nonresponse adjustment weight was included in the analysis.

Subjects were administered a modified version of the CIDI (World Health Organization 1990). The NCS obtained estimates of 14 DSM-III-R diagnoses, including alcohol abuse and dependence, antisocial personality disorder, drug abuse and dependence, dysthymia, generalized anxiety disorder, panic disorder, social phobia, agoraphobia, simple phobia, major depression, and nonaffective psychosis (schizophrenia, schizoaffective disorder, delusional disorder, and atypical psychosis). In addition, to address the ECA finding that psychotic disorders had poor reliability and validity when assessed by nonclinicians (Anthony et al. 1985, Helzer et al. 1985), NCS individuals endorsing psychotic symptoms in the survey were reinterviewed by a clinician with the Structured Clinical Interview for DSM-III-R (Spitzer et al. 1992).

Prevalence
Table 25–5 presents the NCS 1-year and lifetime prevalence rates of the various psychiatric disorders. Lifetime prevalence rates are the proportion of individuals who ever experienced a disorder, and 1-year prevalence represents the proportion of individuals who experienced a disorder in the year before the interview. The lifetime prevalence for any DSM-III-R disorder was 48.7%, and the 12-month prevalence was 27.7%. When grouped by diagnostic category, the lifetime prevalence rates were 24.9% for anxiety disorders, 26.6% for substance abuse and dependence, and 19.3% for affective disorders. As expected, anxiety and affective disorders were more common in women, and substance abuse was more common in men.

Comorbidity
An important focus of the NCS was the assessment of comorbidity. Interestingly, whereas 21% of the sample experienced only one disorder, 14% met criteria for three or more lifetime disorders. Furthermore, among individuals with a lifetime disorder, 53.9% had three or more lifetime disorders. Among individuals with a disorder occurring in the past 12 months, 58.9% experienced three or more disorders. The level of comorbidity was most dramatic for individuals with a severe disorder in the past 12 months, defined as active mania, nonaffective psychosis, or active disorder of other types that either resulted in hospitalization or created severe role impairment. In that subset of respondents, 89.5% had three or more disorders.

Risk Factors and Correlates
The NCS also yielded important data on demographic correlates and potential risk factors for mental disorders. Several earlier patterns of association observed for gender and other characteristics were confirmed. For example, affective disorders occurring in the past 12 months were more frequent in 15- to 24-year-olds, Hispanics, respondents with the lowest income, and respondents who had not graduated from college. Anxiety disorders occurred more frequently in 15- to 24-year-olds, respondents in the three lower income categories (less than $70,000 per annum), and those without a college degree. Substance abuse was found less frequently in African-Americans and more frequently in 15- to 44-year-olds, respondents earning $0–19000 per annum, and non-college graduates. All of these risk factors were also associated with having three or more disorders. No significant results were found for region of the country where the respondent resided (e.g., the Midwest, Northeast, West, and South). However, although residing in a major metropolitan versus a rural area was not a risk factor for the individual disorders, respondents from major metropolitan areas were four times more likely than those from rural areas to have three or more disorders.
Use of Mental Health Services

The NCS also examined the patterns of use of health services by the respondents. Only 40% of individuals with a mental disorder ever received professional care, and only 25% received their care in the mental health specialty sector. On the other hand, 60% of individuals with three or more comorbid disorders received professional help, 40% in the mental health specialty sector. Furthermore, one-third of persons with three or more comorbid disorders received professional help in the past year compared with only 20% of those with one disorder. These findings indicate that the use of health services is concentrated in the segment of the population with a high degree of comorbidity.

Subsequent analyses of service utilization in the NCS have shed light on the magnitude and potential determinants of important subcomponents of the problem of unmet needs for mental health treatment. For example, while only a minority with active major depression received any care in the prior year, an even smaller percentage (7%) received treatment that could be considered minimally adequate (Katz et al. 1998). Even among the extremely vulnerable and impaired population that met criteria for active Serious Mental Illness (SMI), only 40% received any treatment in the prior year (Kessler et al. 2001a). Among NCS respondents with mental disorders who received treatment in the prior year, 19% dropped out prematurely (Edlund et al. 2002).

The National Comorbidity Survey-Replication (NCS-R)

The rapid pace of change in the American mental health care system has made it imperative to reexamine the burdens from mental disorders and their care. Although new forms of treatment have been introduced and promoted, their efficacy and safety have been questioned as well (Food and Drug Administration; Eisenberg et al. 1993, 1998, Leucht et al. 1999, Kessler et al. 2001c, Olsson et al. 2002, Rosenthal et al. 2002, Schatzberg and Nemeroff 2004). Initiatives promoting awareness, detection, help-seeking, and best-practices for mental disorders have been launched but little is known concerning their impacts (Agency for Health Care Policy and Research 1993, Jacobs 1995, Katon et al. 1995, Hirschfeld et al. 1997, National Committee for Quality Assurance 1997, American Psychiatric Association 1998, 2000, 2002, 2004, Lehman and Steinwachs 1998, Wells et al. 2000, Katon et al. 2002). Likewise, effects of the many delivery system, financing, and mental health policy redesigns that have taken place are unclear (Williams 1998, Mechanic and McAlpine 1999, Sturm and Klap 1999, Williams et al. 1999, Weissman et al. 2000, Kessler et al. 2001a, Bender 2002). To shed light on these impacts and to provide up-to-date data on the current burdens from and care of mental disorders in the United States, the National Comorbidity Survey Replication (NCS-R) was undertaken between 2001 and 2003 as part of the larger WHO WMH Survey Initiative.

Design

The NCS-R is a nationally representative household survey of respondents ages 18 and older in the coterminous United States (Kessler et al. 2004). Face-to-face interviews were carried out with 9282 respondents between February 2001 and April 2003. Part I included a core diagnostic assessment administered to all respondents. Part II assessed risk factors, correlates, service use, and additional disorders and was administered to all Part I respondents with lifetime disorders plus a probability subsample of other respondents.
The overall response rate was 70.9%. Diagnoses were made using Version 3.0 of the World Health Organization’s (WHO) CIDI (Kessler and Ustun 2004), a fully structured lay-administered diagnostic interview that generates diagnoses according to the definitions and criteria of both the ICD-10 (World Health Organization 1991) and DSM-IV-TR (American Psychiatric Association 1994) diagnostic systems. Disorders included mood disorders (major depressive episode [MDE], dysthymia [DYS], and bipolar disorder I or II [BPD] studied together for increased statistical power), anxiety disorders (panic disorder [PD], agoraphobia without panic [AG], specific phobia [SP], social phobia [SoP], generalized anxiety disorder [GAD], post-traumatic stress disorder [PTSD], and separation anxiety disorder [SAD]), substance disorders (alcohol and drug abuse and dependence [AA, DA, AD, DD]), and impulse control disorders (intermittent explosive disorder [IED], oppositional defiant disorder [ODD], and attention-deficit/hyperactivity disorder [ADHD]). Blinded clinical reappraisals using the SCID (First et al. 2002) have shown generally good concordance between DSM-IV-TR diagnoses based on the CIDI and the SCID for anxiety, mood, and substance disorders (Haro et al. 2006).

The Early Ages of Onset for Lifetime Mental Disorders

NCS-R estimates of the lifetime prevalence of mental disorders are broadly consistent with those found in previous community surveys in the United States (Kessler et al. 1994, 1998) in showing that half of the general population is affected by mental disorders at some time in their life. Similar to these earlier studies, anxiety and mood disorders are common classes with MDD, SP, SoP, and AA being the most prevalent individual disorders. What may be more surprising, given the paucity of prior lifetime data, is the frequency of impulse control disorders, which have a combined lifetime prevalence that is higher than for either mood disorders or substance disorders.

In addition to their high prevalences, mental disorders examined in the NCS-R are notable for their ages of onset, which are concentrated in the first two decades of life with later-onset disorders largely occurring as temporally secondary comorbid conditions. Consistent with previous epidemiological surveys (Christie et al. 1988, WHO International Consortium in Psychiatric Epidemiology 2000), median ages of onset are earlier for anxiety disorders (age 11) and impulse-control disorders (age 11) than for substance (age 20) and mood disorders (age 30) (see Table 25–6). Such data reveal that mental disorders are uniquely burdensome in that they typically attack youth; almost all chronic physical disorders have conditional risks that increase with age, typically peaking in late middle or old age (Murray and Lopez 1996).

Failure and Delays in Initial Help-Seeking

The NCS-R lifetime data concerning episodes of DSM-IV-TR disorders are highly prevalent during the prior year, affecting over one-quarter of Americans. Although many cases are mild, the prevalence of moderate and serious cases is still substantial, affecting 14.0% of the population. The 5.7% with a serious disorder is remarkably close to the estimated prevalence of Serious Mental Illness (SMI) defined by SAMHSA in the original NCS (Kessler et al. 1996). Consistent with prior studies (Bijl et al. 2003, Demyttenaere et al. 2004), mood disorders have the highest percentage of serious cases (45.0%) and anxiety disorders the lowest (22.8%) (see Table 25–8).

A striking finding from the NCS-R 12-month prevalence data is that more than 40% of cases in the prior year also have comorbid disorders. Patterns of bivariate comorbidity are broadly consistent with the ECA and original NCS in showing that the vast majority of disorders are positively correlated. Relative magnitudes of associations are also quite similar across the three surveys, with high rank-order correlations of odds-ratios among comorbid pairs in the NCS-R versus published odds-ratios (Kessler 1995) in both the NCS (.79) and the ECA (.57). These high levels of comorbidity among cases of 12-month disorders are concerning because NCS-R data also reveal that severity is strongly related to comorbidity. For example, the proportion of 12-month cases having a serious disorder was 9.6% of those with one diagnosis, 25.5% with two, and 49.9% with three or more diagnoses.

The projected proportions of cases that will eventually make treatment contact for each disorder are estimated to be: alcohol abuse (AA), 52.7%; alcohol dependence (AD), 69.8%; drug abuse (DA), 57.0%; drug dependence (DD), 76.9%. (See Color Plate VII)
The Adequacy of Treatment for 12-Month Disorders

NCS-R findings on 12-month use of mental health services shed light on additional forms of poor mental health care in the United States, including underuse, poor quality regimens, use of unproven modalities, and suboptimal allocation of services. On one hand, only 41.1% of those with 12-month DSM-IV-TR disorders used mental health services in the prior year. Among those receiving services, many go outside of health care sectors; for example, complementary-alternative treatments account for 32% of all mental health visits despite a paucity of data supporting their efficacy (Eisenberg et al. 1993, 1998, Weaver 1995, Kessler et al. 2001b, 2001c, Hypericum Depression Trial Study Group 2002, Wang et al. 2003). Furthermore, only 32.7% of treated patients with disorders were classified as receiving at least minimally adequate treatment in the prior year (see Table 25–9). The probability was lowest in the General Medical sector (12.7% vs. 44.5% in the Psychiatrist sector and 46.5% in the Nonpsychiatrist Specialty sector). This finding is of concern in light of a shift that appears to be occurring between sectors, with expanded use of the general medical sector for mental health services (by 17.9% of NCS-R respondents vs. 13.3% a decade earlier in the original NCS) (Kessler et al. 1999).

Future Directions

As outlined in this chapter, progress in enumerating the rates of mental disorders in adults in the general population, and documenting the extent of unmet need, has been extensive. However, considerable additional work remains for psychiatric epidemiologists in the future (Kessler 2000).

Perhaps the most fundamental work that is needed is ongoing refinement of our current conceptualization of mental disorders. Important questions have been raised by the high rates of mental disorders observed in recent population-based surveys, including whether there may have been overdiagnosis among individuals with clinically insignificant symptoms (Regier et al. 1998, Narrow et al. 2002). In part, because of such concerns, new requirements that symptoms be clinically significant were added to many disorder criteria in DSM-IV-TR. However, far from settling the issue, these new requirements have themselves sparked a healthy debate (Spitzer 1998).

A closely related topic of considerable importance is whether mental disorders would be better conceptualized dimensionally as occurring on a continuum, rather than categorically as “cases” and “noncases.” Researchers and clinicians may ultimately find that the two conceptualizations are far from mutually exclusive and, in fact, highly complementary. For example, adding the dimensional view to the currently prevailing categorical view of mental disorders, allows identification of subsyndromal psychopathology in individuals who may later develop full-blown disorders. Another advantage of adding a dimensional conceptualization is that it could provide compelling arguments against the stigmatization that comes from rigid distinctions between the normal and pathological.

*Projections based on time-to-contact survival curves in Figures 25–1–25–4.
†Weighted number of respondents with a lifetime history of the disorder.
Results of future psychiatric epidemiologic studies will only be as good as the instruments that are used for the assessment, the memories of the respondents who are asked to recall their internal states throughout their lifetimes, and the willingness of subjects to divulge sensitive and potentially stigmatizing symptoms. Until we have a means of verifying self-reports against a gold standard, improvements in measurement will be needed (Fennig and Bromet 1992). In addition to developing new instruments and establishing their psychometric properties, the advantages and limitations of several new low-cost modes of administering surveys (e.g., via interactive voice-response telephone technology, computerized self-assessments, and the Internet) should be explored as well.

Data from future longitudinal studies will be especially important. Only longitudinal studies can shed light on both the natural history of disorders as well as the extent to which early treatment can mitigate the course of psychiatric disorders.

†Assessed in the Part II sample (n = 5692)
‡Assessed in a random one-third of the Part II sample (n = 1808)
§Assessed in the Part II sample among respondents aged 18–44 years (n = 3199)
¶Estimated in the Part II sample. No adjustment is made for the fact that one or more disorders in the category were not assessed for all Part II respondents.
The estimated prevalence of any impulse-control disorder is larger than the sum of the individual disorders because the prevalence of intermittent explosive disorder, the only impulse-control disorder that was assessed in the total sample, is reported here for the total sample rather than for the subsample of respondents among whom the other impulse-control disorders were assessed (Part II respondents in the age range 18–44). The estimated prevalence of any impulse-control disorder, in comparison, is estimated in the latter subsample. Intermittent explosive disorder has a considerably higher estimated prevalence in this subsample than in the total sample.

and avert long-term disabilities. Longitudinal studies can also help answer questions concerning the temporal relationship between disorders, such as which disorders are primary in patients with comorbidity (e.g., both mood and substance disorders) or how transitions can occur between disorders. Such studies are also critically needed to identify early signs and symptoms that predict the subsequent onset of disorders, which can then, be used in future primary prevention efforts. Longitudinal studies are also critical to improve the adequacy of treatment. In the industrial quality sciences, repeated application of data collection using consistent methods is an integral part of continuous cycles of improvement (Berwick 1989). While analogous cycles of continuous quality improvement have been called for in health care, they have failed to take hold especially in the general population, in part, because of the lack of the requisite longitudinal data collection on which the process depends (Blumenthal 1995, Blumenthal and Kilo 1998). Examination of temporal trends between the original NCS and NCS-R have already shown lack of change in disorder prevalence (Kessler et al. 2005) and suicidality in the United States (Kessler et al. 2005), suggesting efforts and changes in the past decade have not been sufficient. Such comparisons between the original NCS and NCS-R provide evidence that longitudinal application of population-based psychiatric epidemiologic surveys hold great promise for identifying and reducing burdens as well as understanding and improving poor-quality care. Repeating population-based surveys using consistent methodology can serve as the nation’s quality improvement and assurance system.

Additional research shedding light on the epidemiology of mental disorders in special populations needs to be undertaken. For example, greater enumeration of mental disorders in children and the identification of modifiable, early-life risk factors for the development of subsequent mental disorders in adulthood, are especially important areas. However, such research will require advances in the nosology of psychopathology in childhood and adolescence, the development of means to accurately combine information provided by children with responses from other informants, and the development of new methods to overcome the potentially long periods of observation needed before many disorders onset in prospective studies (Kessler 2000). Further psychiatric epidemiologic study of the elderly is also needed and would benefit from advances in obtaining accurate retrospective recall of aspects of mental disorders from earlier decades, especially under circumstances of potentially diminished cognition.

In addition to these needs in descriptive epidemiology, there is a need to expand our knowledge from a clinical epidemiology perspective. Whereas community studies now use sophisticated sampling techniques and state-of-the-art assessment tools, many clinical studies of onset and course suffer from poor sampling schemes and psychometrically unproven measurement tools. For example, the majority of clinical studies rely on consecutive admissions rather than first-episode or even first-admission samples, introducing the potential for bias by chronically ill users of service (Cohen and Cohen 1984). Thus, conditions such as nonaffective acute remitting psychosis, found in patients in the first-contact study of the World Health Organization, have gone unnoticed in clinical research conducted in the United States (Susser and Wandinger 1994). Identifying samples at the time of their first episode of disorder is crucial for understanding such basic issues as the course of alcohol abuse or the course of major depression, and the risk factors associated with better or worse prognosis.

Such future clinical epidemiologic research will require new methodologic advances on several fronts. For example, Fennig et al. (Fennig et al. 1994) have shown that the initial diagnosis in a first-admission psychotic sample is difficult to determine (primarily because of substance abuse comorbidity) and can change over time. Such diagnostic instability causes first-admission samples selected on the basis of a cross-sectional diagnosis to contain false-positives and exclude potential false-negatives. The false-positives are not a major problem because individuals later discovered to have a different disorder can be dropped from a study. The false-negatives are a greater impediment because they will have been excluded from the sample even though their symptom pattern might evolve into the disorder. Longitudinal approaches to diagnosis will need to be implemented, as was done in the study by Tohen et al. (Tohen et al. 1990, 1992) of outcome in mania.

Understanding the treatment needs of individuals in the general population who are found to have diagnosable mental disorders and characterizing the treatment experiences of the chronically mentally ill should also remain a high priority. While earlier surveys have revealed enormous unmet needs for treatment, information on the pathways into and through formal and nontraditional sources of care, and the extent to which individuals with mental disorders take steps on these pathways is very limited. Mental health services research will need to identify actionable barriers that prevent access to care. Because effective treatment also requires adequate treatment intensity and duration, investigators will need to understand and improve adherence to treatments that are initiated. With growing constraints on health care resources and the rising popularity of certain psychotropic medications, research on inappropriate use, overuse, and the cost-effectiveness of treatments is certain to increase in importance in the future as well.

Most psychiatric epidemiological studies of risk factors have investigated psychosocial and demographic risk factors and failed to consider potential familial and biological variables. Progress has been made to integrate familial variables, although the sources of information on familial mental disorders have often been meager and inadequate. Meanwhile, biological research has often relied on small, clinically diagnosed samples. It seems timely to consider the complex interplay between psychosocial and biological variables and better integrate the two types of risk factors’ research under a single umbrella.

Psychiatric epidemiologists strive to identify the causes of mental disorders with the ultimate goal of designing and targeting the application of interventions for primary and secondary disease prevention. Interventions suggested by the results covered in this chapter include those to increase access and initiation of treatments, such as renewed community awareness and screening programs, new means for financing mental health services, and expansion of treatment resources for underserved areas (Jacobs 1995, Hirschfeld et al. 1997, Mechanic and McAlpine 1999, Kessler et al.
Future interventions also clearly need to focus on improving the intensity and effectiveness of care that is given to patients with mental disorders. A related challenge is understanding why non-health care treatments such as CAM have such great appeal and whether legitimate aspects of this appeal (e.g., greater patient-centeredness) can be adopted in evidence-based treatments. Proven disease management programs that enhance treatment adequacy and adherence (Katon et al. 1995, Wells et al. 2000, Schoenbaum et al. 2001, Simon et al. 2001, Katon et al. 2002) as well as establishing performance standards hold promise for enhancing treatments and monitoring the impacts of interventions in the future (Substance Abuse and Mental Health Services Administration 1996, National Committee for Quality Assurance 1997). However, increasing uptake of such successful programs and treatment models will almost certainly require addressing existing barriers, such as competing clinical demands and distorted incentives for effectively treating mental disorders, as well as providing purchasers with metrics to help them understand what their return-on-investment (ROI) will be for improving mental health service use in America (Klinkman 1997, Williams 1998, Williams et al. 1999, Frank et al. 2003, Pincus et al. 2003, Wang et al. 2003).

A final way in which psychiatric epidemiology can become a uniquely powerful tool is when data from the United States are pooled, supplemented, and compared with comparable data from other countries. Policy makers need specific designs they can implement to achieve their goals. Some techniques employed in managed care systems (e.g., gatekeeping, increased cost-sharing, utilization review, prior approval, etc.) could presumably be brought to bear on unnecessary use but not underuse—in fact, they may worsen unmet needs for treatment. The impacts of other policies, delivery system features, and means of financing that policy makers could implement are essentially unknown (Burgess et al. 2004). For these reasons, collection of detailed data on the mental health policies, delivery system features, and means of financing mental health care in different countries is a promising area for future research (Saxena et al. 2003). When merged with psychiatric epidemiologic data on mental disorders and treatments, such combined data could shed light on the impacts of policies, delivery system, and financing features, and help policy makers choose ones that achieve their desired goals (Mezzich 2003). These are but a few of the many contributions from psychiatric epidemiology that will be needed to achieve the laudable goals set forth in the recent President’s New Freedom Commission for alleviating the tremendous burden from mental disorders (President’s New Freedom Commission on Mental Health).

Introduction
Cognitive psychology and more recently cognitive neuroscience are among the dominant models people use to view themselves, in both health and illness. News media constantly publicize evidence of neural bases for the processes that make us human, such as memory, emotion, and self-regulation. Similarly, the public increasingly considers psychiatric illness through the lens of cognitive and neural dysregulation, and patients themselves use the language of neuroscience and cognitive psychology to describe their symptoms as rooted in brain disruption and problematic ways of thinking (Luhrmann 2001). Finally, treatment options employed by psychologists and psychiatrists have changed drastically with the application of cognitive models. Cognitive behavioral therapy has proven to be as efficacious in the treatment of depressive symptoms and more efficacious in preventing relapse than pharmacological treatments (Beck 1976, David 2004, Hollon et al. 2006). Currently, there is an increasing emphasis on assessing the effect of pharmacological interventions on the cognitive processes believed to underlie daily functioning in people with debilitating psychiatric disorders such as schizophrenia (Green 2007).

This chapter will provide an outline of basic cognitive processes and the brain structures responsible for them. For each core process described here, we will provide examples of psychiatric conditions that involve disruption of that process as well as a brief consideration of treatment implications. Given the constraints of a single chapter, our description of core processes and their relevance to disorders and their treatment is necessarily selective. We begin with a brief history of the origins of modern cognitive psychology and then discuss the rationale for viewing cognition as a set of modular, yet connected, functional information-processing steps rooted in the brain.

Historical Review of the Cognitive Framework
Although the empirical and theoretical study of cognition dates back over a century (Ebbinghaus 1885/1964, James 1904), our modern view of cognition is far more recent. For almost the first half of the twentieth century, cognition—the internal processes that occur between an organism’s exposure to a stimulus and its response—was largely ignored in favor of observable behavior. In fact, cognition was often viewed as epiphenomenal, a side effect of the relationship between stimuli and responses, which in itself had little impact or consequence. Two major trends sparked the rebirth of cognition as a topic of central interest in psychology. The first was the inability of behaviorism to describe language production, which demonstrated complexities greater than would be expected by stimulus–response relationships (Chomsky 1959). The second was the appearance of a compelling model to replace behaviorism: the analogy of the human mind to a computer.

The Mind–Computer Analogy
Computer technology developed at an incredible rate beginning in the late 1940s and captured the attention of the general public and psychologists alike. As championed by Newell and Simon (1972), among others, comparisons between human cognitive functioning and computers advanced the understanding of cognition in at least two significant ways. The first is that both the human minds and the computers operate through information processing: the storage, manipulation, and transformation of information. These steps were ignored in behaviorism, but application of the computer analogy suggested that they could be studied empirically. The analogy was especially apt for conceptualizing such processes as the storage and retrieval of information from memory, the allocation of attention, and problem solving.
The second advancement in the understanding of cognition brought about by the mind–computer analogy was the conceptualization of cognition at multiple levels of analysis, from the concrete and materialistic to the more abstract. For example, a computer can be understood in terms of its hardware—the physical structures through which information passes, which constrain the processing steps available to it—or in terms of its software—the functions it is programmed to use to manipulate information. These two levels of analysis interact with and depend on each other for a complete understanding of a computer’s processes. Similarly, cognitive processes can be described as the communication between populations of neurons, or as the transformation of information. Both of these levels of analysis are modular or comprised of multiple, separable components (Fodor 1983). A cognitive psychologist describing long-term memory will appeal to multiple steps necessary for encoding, some of which are independent of each other. A functional neuroanatomist would similarly describe multiple brain regions involved in memory, also in some cases working independently. Cognitive and neural levels of analysis can be fruitfully applied to the same cognitive cases working independently. Cognitive psychologists describing long-term memory will appeal to multiple steps necessary for encoding, some of which are independent of each other. A functional neuroanatomist would similarly describe multiple brain regions involved in memory, also in some cases working independently. Cognitive and neural levels of analysis can be fruitfully applied to the same cognitive cases working independently. them in turn. We focus mainly on what are known as higher-level cognitive processes (attention, executive functioning, memory and mental representation, and social cognition), because much of the research on the cognitive bases of psychiatric difficulties has focused on these processes. However, we note that difficulties in lower-level cognitive processes such as the early stages of transforming sensory input into perceptions and the general speed of sensory information processing have been implicated in disorders involving pervasive cognitive difficulties. For example, schizophrenia appears to involve a core inability to gate or inhibit new information until current sensory information has been sufficiently processed, as well as a generally slower speed of information processing (Walker et al. 2004).

Throughout the chapter, we emphasize the integration of cognitive with emotional processes. Although once viewed as distinct phenomena having little to do with each other, a growing literature has made clear the fact that emotion interacts with and influences every facet of cognition in ways that are relevant for psychopathology. Emotional stimuli capture attention (Moray 1959, Nummenmaa et al. 2006), enhance memory (LaBar and Cabeza 2006), and affect decision making (Greene et al. 2001, McClure et al. 2004). Cognitive control efforts can be hijacked by emotion, and, through executive processes, emotion can be enhanced or diminished (Ochsner and Gross 2005, Ochsner et al. 2004b). As such, emotion may most efficiently be described as an overarching part of many cognitive processes, rather than its own modular component process.

Attention

Attentional Filters and Attentional Capture

The brain is constructed to carry out many functions in parallel. Yet, there is a limit to the amount of sensory information it can meaningfully process, and so conscious processing must often work in serial (Sternberg 1966). Given that our resources are inadequate for processing everything in the environment, we use attentional filters to select which stimuli to focus on (Broadbent 1958, Treisman 1969). Research on attention has emphasized three facets of selective attention: an alerting system that can be harnessed to achieve and maintain sensitivity to certain incoming stimuli, an orienting system involved in the selection of information from sensory input, and an executive system that monitors and resolves conflict among thoughts, feelings, and responses to help ensure attention to selected stimuli. Evidence supporting attentional filters comes primarily from studies in which participants are presented with competing stimuli and asked to attend to only one of multiple channels (e.g., auditory or visual; Neisser and Becklen 1975). During such tasks, participants fail to encode information coming from the unattended channel. Under certain conditions, most participants will ignore even striking visual information, such as a gorilla walking through a hallway (Simons and Chabris 1999).

Yet unattended information is not lost to awareness and can still have an impact on behavior. For example, when people are asked to make lexical decisions about whether an attended homonym belongs to a category (e.g., deciding if “bear” is an animal), their performance is facilitated by unattended category-relevant cues (e.g., “hibernate”) and inhibited by irrelevant cues (e.g., “naked,” which suggests an alternate meaning of the homonym; see Johnston and Wilson 1980). Furthermore, salient or distinctive unattended stimuli have a particularly strong effect on perceptual tasks and are easy to find regardless of the number of distractors present (Shiffrin and Gardner 1972), suggesting that they “capture” attention even when being willfully ignored (Remington et al. 1992, Yantis and Hillstrom 1994).

How can nonattended, willfully ignored cues affect behavior? One theory is that during many tasks investigating attentional capture, salient distractors are presented repeatedly, causing participants to expect them. This expectancy may create a bias toward perceiving unattended stimuli and cause subjects to regularly switch their attention from attended to unattended-but-expected stimuli (Simons 2000). The fact that expected stimuli are particularly likely to capture attention is relevant to the attentional biases shown by people with anxiety disorders and depression (discussed below).

Neural Basis of Attention

Neuroimaging studies of attention in healthy humans have focused primarily on demonstrating that engagement of the sensory cortex in processing stimuli is attention dependent (see Figure 26–1 and Table 26–1): that is, even the most basic perceptual experience (e.g., visual processing) can be amplified or diminished by the presence or absence of attention. These studies show that attention modulates neural activity in the sensory cortices related to vision (McMains and Somers 2004, Somers et al. 1999), audition (Jancke et al. 1999), touch (Johansen-Berg et al. 2000), and pain (Bantick et al. 2002). Furthermore, both attention and enhancement of basic sensory activity increase later explicit and implicit memory for stimuli (Vuilleumier et al. 2005). However, a true understanding of the effects of attention requires a theory about the cognitive and neural mechanisms that cause attention to be directed toward goal-relevant stimuli. For example, emotional or self-relevant information tends to capture attention (Moray 1959), and neuroimaging studies have demonstrated that fear-related stimuli can trigger affect-related activity in the brain even when presented preattentively and masked by nonemotional stimuli (Whalen et al. 1998, 2004).

Attentional Difficulties in Psychiatric Disorders

Attentional difficulties have been examined in two ways. First, basic problems in the alerting, orienting, or executive control systems have been identified in a variety of disorders (see Posner and Rothbart 2007). For example, difficulties in the alerting system have been found in normal aging and in attention-deficit disorder. People with autism show a dampening in the orienting system relative to normal control subjects for both social and nonsocial stimuli. People with schizophrenia and Alzheimer’s disorder show difficulties in maintaining attention on particular stimuli in the presence of distractor stimuli, potentially helping explain their difficulties in staying on track in conversations and the tasks of daily life.

Second, specific types of biases in attention have been identified (see Mathews and MacLeod 2005, for a recent review). Such biases are to be expected, given basic evidence that the allocation of attention to particular types of stimuli is influenced by their importance to the individual (i.e., expectancies for particular stimuli to be of consequence...
for the self, developed through the individual’s cognitive-social learning history) and by current mood states. For example, when dispositional and contextual factors increase the extent to which an individual expects negative outcomes (e.g., harm, social rejection, and failure), he/she becomes more susceptible to attentional capture by cues consistent with those negative expectations, with implications for mood, thought patterns (e.g., rumination), and memory. Furthermore, the fact that attentional capture can occur outside of conscious awareness implies that vulnerability to this phenomenon is not entirely under the individual’s control. For example, recovering addicts exposed to people, places, or things associated with the object of their addiction may have their attention captured by cues that trigger relapse behavior, despite their best intentions.

The association between anxiety and attentional disruption by threat stimuli is well established by evidence from several experimental paradigms. In tasks that make conflicting demands on attention (e.g., the Stroop task, which is described in more detail below), research has demonstrated attentional draw by threat-related stimuli in social anxiety (Grant and Beck 2006, Spector et al. 2003) and generalized anxiety (Taghavi et al. 2003). To further determine the nature and time course of attentional disruption by various kinds of stimuli (e.g., words or pictures with threatening, neutral, or pleasant content), researchers have employed variations of dot-probe and exogenous cueing tasks that assess attention by measuring how quickly the individual responds to a visual cue that appears in the location of the stimulus versus another location. Studies have demonstrated that stimuli relevant to threats of potential rejection have a disruptive effect on attention for people high in rejection sensitivity and insecure attachment (Berenson et al. 2007, Dewitte et al. 2007), social anxiety and clinical social phobia (Garner et al. 2006, Mogg et al. 2004b, Musa et al. 2003), posttraumatic stress disorder in abused children (Pine et al. 2005), and generalized anxiety disorder (Bradley et al. 1999). The fact that the attentional bias associated with anxiety occurs even during masked exposures to threat stimuli suggests that it is immediate and relatively automatic.

Figure 26-1 Some of the brain regions and cognitive processes involved in attentional deployment and executive function. Darkly labeled regions are targeted by lightly labeled ones, according to the theory of Miller and Cohen (2001), as well as others. Note that regions that are not shown would not be visible from the surface because they are located subcortically. FEF, frontal eye fields; TPJ, temporal parietal junction; IFG, inferior frontal gyrus; DLPFC, dorsolateral prefrontal cortex; ACC, anterior cingulate cortex; SC, sensory cortices. (See Color Plate VIII)
Depression has also been associated with distinct attentional biases. Relative to the immediate bias associated with anxiety, the attentional bias associated with depression appears to occur at a later stage, suggesting the involvement of more strategic processes (Mathews and MacLeod 2005). Compared to nondysphoric individuals, those with major depression show delayed disengagement of attention from negative stimuli (Koster et al. 2005, Leyman et al. 2007). Individuals with current and/or remitted depression also attend to depressogenic stimuli such as negative words and sad faces more than to happy stimuli (e.g., Gotlib et al. 2004, Joormann and Gotlib 2007, Ladouceur et al. 2006). Some evidence suggests that the pattern of focusing attention on negative versus positive stimuli may predate the development of depression in individuals at high familial risk (Joormann et al. 2007) and may also persist after remission (Paelecke-Habermann et al. 2007). In another study, the persistence of attentional bias for sad faces after current depressive symptoms were controlled was predicted by chronic “ruminative brooding” (Joormann et al. 2006).

**Implications for Therapeutic Intervention**

An intervention targeting attention is usually basic to all cognitive therapy exercises and techniques: that is, individuals are taught to monitor specific thoughts, feelings, and behaviors relevant to the symptoms targeted for change and to keep structured records of these processes. By learning to do this, individuals not only attend to and become more aware of the cognitive and situational antecedents of problematic behaviors, but are also forced to take notice of the positive (or less negative) aspects of their lives, such as when negative expectations and beliefs are disconfirmed, a feared situation is tolerated without catastrophe, a pleasant activity succeeds in temporarily improving mood, or an urge to engage in self-defeating behavior is successfully resisted. Attentional biases often lead individuals to overlook these positive developments, so they miss out on these reasons for hope and opportunities to learn from success. An important feature of the detailed monitoring and record-keeping characteristic of cognitive therapy is to help increase access to overlooked information so as to counteract attentional biases and, in the case of psychotic disorders, provide evidence for use in reality testing. Cognitively trained psychologists have also begun to develop computerized exercises that aim to reduce negative attentional biases, through repetitive practice attending to positive stimuli (Dandeneau and Baldwin 2004). Future interventions for attentional biases are likely to increasingly involve computerized cognitive remediation tasks like these.

**Top-Down Control of Attention and Executive Functions**

Theories of attention tell us about the processes involved in extracting discrete meaning from a wild abundance of sensory information. However, the ability to filter out competing stimuli by their perceptual differences from targets by itself is not enough by itself to facilitate goal-related behavior. As Desimone and Duncan (1995) put it: “an attentional system… would be of little use if it were entirely dominated by bottom-up biases” (p. 199). Of particular interest to psychopathology and therapeutic intervention is an understanding of how “top-down”, controlled processes work to guide attention toward goal-relevant stimuli. The study of working memory and executive function has explored how the brain transforms goals into adaptive deployment of attention, memory encoding, and inhibition of nonrelevant stimuli. These processes are highly relevant to many psychiatric disorders, which often include failures to inhibit irrelevant thoughts and percepts, or difficulties staying “on task.”

The term “top-down” or “controlled” processing refers to cognition that meets the following four criteria: it is relatively slow compared to automatic processing; it is effortful and susceptible to interference from competing tasks; it occurs in a serial, as opposed to parallel, fashion; and it is flexible, being easily adjusted to meet current goals. Perhaps predictably, “bottom-up” or “automatic” processing is considered to be any type of cognition that meets the opposite criteria. Many dual process models have explored the distinction between types of processing (Chaiken and Trope 1999, Wegner and Bargh 1998), but in order to understand how these models apply to directing attention, we can use an example dating back to the first half of the twentieth century.

Perhaps the single most famous example of the need for top-down control over attention comes from the Stroop task, invented over 70 years ago and named after its originator (Stroop 1935). The task requires participants to read a list of colors aloud as quickly as possible. In one condition, each word is printed in the color congruent with its name (i.e., “red” is printed in red). In another, words are printed in incongruous colors (i.e., “red” is printed in blue). Participants must sometimes read the word in print, and other times must indicate the color the ink use to print the word. This task requires participants to use multiple top-down control processes, many of which are also needed when trying to solve problems, to study for examinations, or even to control emotional responses (see below). These processes can be broadly split into two categories: (1) maintenance and manipulation of relevant information, (2) controlling attention and responses based on this information. In the following sections, we will discuss each of these processes, drawing on the classic example of the Stroop task to illustrate them.

**Executive Control of Attention and Working Memory**

(1) Maintenance and manipulation of relevant information in working memory. Before a participant in the Stroop task begins reading words or colors, he/she must actively have in mind—in working memory—the correct type of information to focus on (i.e., “words” or “colors”). The distinction between active, short-term retention of information and long-term storage has been recognized for over a century. Current models describe short-term or working memory as a set of processes for storing and manipulating a limited amount of information needed to accomplish a goal (Baddeley 1992, 2003, Baddeley and Hitch 1974). Working memory includes three modules mediated by activity of the prefrontal and parietal cortices: two modules that store and...
maintain spatial and verbal information, and a third module, the central executive. Current theory and evidence indicate that the central executive interacts with other executive functions to select, maintain, and manipulate goal-relevant information in the other two modules and that these processes occur in the prefrontal cortex (Braver and Bongiolatti 2002, Braver and Ruge 2006, Smith and Jonides 1999).

Specific executive processes include allocating to, updating, and manipulating information stored in the buffers, as well as protecting their contents from interference and maintaining temporal coding. Studies of single neurons in monkeys and neuroimaging in humans both show that the inferior frontal cortex remains active in the interval between a subject learning information and the subject using that information in a response (Cohen et al. 1997, Funahashi et al. 1989). An individual’s ability to hold in mind the correct set of information to respond to during the Stroop task thus depends on these processes of working memory.

(2) Executive function in controlling attention and selecting responses. Once relevant information is selected and maintained by working memory, how does a Stroop task participant ensure that this information assists in quick and accurate responses? A major theory proposed by Miller and Cohen (2001) suggests that the prefrontal cortex is again centrally involved and that it works to strengthen connections between relevant stimulus features and responses. For example, during incongruent trials on the Stroop task, a participant may see the word “red,” printed in green, and have to read the name of the color. In this situation, the color in which the word is printed and the word itself compete for the participant’s attention and response. The conflict between possible responses is detected and monitored in the anterior cingulate cortex surrounding the corpus callosum (Botvinick et al. 2001, Bush et al. 2000, Carter et al. 1998), which then can recruit more executive control from the prefrontal cortex. The prefrontal cortex, in turn, biases perception of incoming information toward relevant cues (i.e., the shape and order of letters; see Miller and Cohen 2001). Recent evidence suggests that during visual search, this process is fundamentally sensory. That is, the prefrontal cortex actually intensifies brain activity in regions related to perceiving relevant visual cues, causing them to “pop out” more easily in attention (Egner and Hirsch 2005).

Role of Inhibition in “Top-Down” Processing

Control of Prepotent Responses

If top-down processing during the Stroop task biases attention toward the goal-relevant aspect of a stimulus (the letters and words themselves), what is the cognitive and neural fate of goal-irrelevant or distracting stimuli (in this case, the color that the words are printed in)? According to Miller and Cohen (2001), irrelevant stimuli are inhibited at multiple levels, allowing their effect on behavior to be minimized. This inhibition can be incidental: since irrelevant stimuli are unattended, they may be processed less strongly by the sensory cortex (see the “Attention” section above) and also produce less of an effect on memory (see the “Memory” section below). However, inhibition can also be active and effortful, as when people attempt to stop themselves from performing a “prepotent” or preferred response, such as naming the color a word is printed in, hitting the gas pedal when a light turns green, or (for some people) smoking a cigarette after dinner. Several lines of research have studied inhibition, finding that it is often quite successful and that it relies on the same top-down processing mechanisms—instantiated in the lateral prefrontal cortex—that underlie other aspects of executive function. Such studies have most often used “Go–No-Go” paradigms in which participants have to respond to most letters as quickly as possible and—if a certain letter appears—to stop themselves from responding. Such studies (and those using the related stop signal task) have found that the lateral frontal cortex is necessary for such inhibition (Aron et al. 2004, Aron and Poldrack 2006). Research on drug abuse has found impaired inhibitory performance in individuals who abuse cocaine, as well as abnormalities in activation of the anterior cingulate (also necessary for executive function) during inhibitory control tasks (Hester and Garavan 2004). Inhibitory control may also be affected in other psychiatric disorders such as schizophrenia (Barch 2005a).

Control of Memory and Emotion

Other applications of executive control have particular clinical relevance. For example, frontally mediated executive control processes are recruited for the regulation of emotional responses. If instead of using words, a Stroop task is designed such that participants must ignore the negative or positive valence of a word in order to respond quickly, similar behavioral and neural effects predict their success at screening out such information (Compton et al. 2003, Etkin et al. 2006). Furthermore, the ability to “tune out” emotional information in such tasks (and the associated anterior cingulate and prefrontal activation) is impeded in posttraumatic stress disorder (Shin et al. 2001) and other anxiety disorders (Bishop et al. 2004).

Moving beyond reaction time differences in affective Stroop tasks, prefrontal executive processes are also involved in consciously regulating emotional responses to affectively laden stimuli. The motivation to study such processes comes from a long-standing literature on emotional appraisal. Appraisal theory posits that bottom-up emotional responses to stimuli (such as autonomic arousal) are relatively undifferentiated and by themselves cannot create an entire emotional experience. Instead, some interpretation (or appraisal) is a necessary step in the experience of emotion. In support of this idea, empirical work has demonstrated that top-down appraisals of emotional stimuli are necessary to the experience of emotions (Lazarus 1991, Scherer et al. 2001) and can affect physiological responses to emotional stimuli (Pecchinenda 2001). Emotional appraisals can also affect interpretations of external or internal emotional cues, such as whether physiological arousal is experienced as elation or anger (Schachter and Singer 1962). Following general appraisal theory, a related literature has explored the effects and neurocognitive bases of “reappraisal,” or top-down regulation of emotional responses. In a common paradigm, participants are asked to reappraise an emotional stimulus so that it will affect them less. Behavioral and psychophysiological studies have shown that, indeed, top-down reappraisal can affect emotional responses (Gross 1998, 2002, Lazarus and Alfer 1964, Richards and Gross 2000). More recent neuroimaging studies have shown that such reappraisal depends on brain systems quite similar to those involved in executive control (Beauregard et al. 2001,
Problems of Executive Functioning in Psychiatric Disorders

Effective executive functioning (alternatively termed self-regulation) can be viewed as involving the ability to activate and deploy psychological mechanisms that enable the inhibition of stimulus-driven, emotion-laden responses under stress in a flexible manner, taking into account the current situation's demands and one's long-term goals. Thus, to be considered effective, the executive or self-regulatory system involves self-regulation that is flexible, strategic, and discriminative. Importantly, deficiencies in the system can involve over- as well as undercontrol. A regulatory system involving overcontrol may contribute to the relatively inflexible strategy of avoiding exposure to social threat that characterizes social phobia or the reclusive behavior of some people with schizophrenia, for example. In contrast, undercontrol characterizes the impulsive behavior of people with borderline personality disorder, antisocial personality disorder, and other disorders involving approach/appetitive behavior (such as the manic phase of bipolar disorder and addictive disorders).

A number of different forms of difficulties have been studied in relation to various disorders. These include: (1) Difficulties maintaining attentional control when processing conflicting stimuli, often assessed in a basic visual discrimination task in which participants identify the direction of a target arrow that is surrounded by flankers arrows in the conflicting versus congruent direction (e.g., Posner et al. 2003). (2) Difficulties in behavioral inhibition, that is, in the ability to stop oneself from impulsively behaving in ways that have negative consequences. This ability is often assessed using the passive avoidance learning task, involving a Go/No-Go task in which study participants learn by trial and error to press a button when some stimuli appear and refrain from pressing it when other stimuli appear (Newman and Schmitt 1998). (3) Difficulties flexibly adapting behavior to changes in reward and punishment contingencies over time, an ability that requires both properly calibrated monitoring of these contingencies and the ability to use them to respond strategically. Difficulties in this area characterize many forms of maladaptive behavior, such as when someone persists with a behavior pattern long after its cost/benefit ratio has plummeted, or when someone fails to strategically pursue long-term goals because they too readily alter their course when minor setbacks or tempting distractions arise. The probabilistic reversal task (Hornak et al. 2004) taps the ability to adapt to new contingencies and extinguish prior response patterns as necessary.

These types of difficulties may reflect a basic failure of executive functioning or a vulnerability of otherwise adequate functioning to being overwhelmed under conditions of emotional arousal. In the case of most disorders, research to address this question has either not been undertaken or yielded inconclusive results.

Protective Role of Effective Executive Functioning

Beyond its direct effects on specific psychiatric symptoms and disorders, executive functioning may have important effects on psychopathology as a moderator of the impact of other vulnerabilities. For example, the heightened vulnerability for certain forms of psychopathology associated with such risk factors as temperamentally high emotionality, exposure to adversity in early attachment relationships, chronic or traumatic stress, or conduct-disordered peer influences may be reduced or neutralized in individuals with sufficient executive capacity to optimally regulate emotion, resist impulsive decisions that would expose the self to further risks, and plan for the future.

Evidence for such a moderation effect of executive functioning has been found in people at risk of emotional and interpersonal difficulties because of heightened sensitivity to interpersonal rejection. This defensively motivated disposition encompasses a tendency to anxiously expect, readily perceive, and react intensely to cues of rejection and has been shown to increase vulnerability to interpersonal aggression, depression, substance use, social avoidance, and borderline personality symptomatology (Pietrzak et al. 2005). Effective executive functioning has been shown to either reduce or neutralize the vulnerabilities associated with rejection sensitivity in several studies. In one study, executive functioning was indexed by the amount of time a 4-year-old child spent waiting for a larger, preferred reward rather than opting for an immediately available smaller one (Ayduk et al. 2002). This delay ability reflects the competency to disengage attention from emotional information that typically induces a here-and-now mindset and to inhibit a dominant, prepotent response in favor of a less accessible, subdominant response that is more adaptive (see Mischel and Ayduk 2004 for review). When study participants were subsequently reassessed at the age of 28 years, rejection sensitivity was related to negative self-image, drug use, ineffective coping, and educational achievement only among participants who had difficulty delaying gratification at the age of 4 years (Ayduk et al. 2000, Study 1). Recently, Ayduk et al. (in press) extended these findings to symptoms of borderline personality disorder.

In line with these findings, Judd (2005) has argued that neurocognitive impairment (either genetic or acquired) may represent a central factor determining whether children in abusive family environments develop borderline personality disorder, because such impairment would exacerbate the negative impact of insecure attachment on metacognitive processes involved in self-regulation. In a related vein, evidence suggests that high baseline IQ (which reflects a general cognitive ability including executive functioning) can help protect trauma-exposed individuals from developing posttraumatic stress disorder (Macklin et al. 1998, Silva et al. 2000). Executive functioning is likely to be a key moderator of the links between risk factors and other forms of psychopathology as well.

Implications for Therapeutic Intervention

Several cognitive therapy interventions target problems in self-regulation. Monitoring of thoughts and feelings around
problematic impulsive behaviors such as occur in conduct disorder, substance abuse, or binge eating helps to identify modifiable triggers and increase the period of controlled cognitive processing preceding behaviors that might otherwise occur immediately upon impulse without thought of the consequences. In addition, mindfulness-based cognitive treatments have been developed to help individuals with such conditions as borderline personality disorder (Linehan 1993) and major depressive disorder (Segal et al. 2001) gain distance from their immediate feelings, thoughts, and urges. Mindfulness involves the ability to simply notice thoughts and feelings without feeling involved in them or compelled to act on them. Meditation exercises in which the individual practices maintaining control of their attention and shifting it away from self-defeating thoughts and urges constitute an important part of this approach, and there is evidence that meditation increases control over attention (Slagter et al. 2007).

Computerized attention training exercises have also been shown to increase executive control, as well as IQ and brain development in children (Rueda et al. 2005), and may have utility in cognitive treatment for impulsive behavior disorders. Attentional control training has also been employed in the treatment of schizophrenia, with the aim of reducing cognitive deficits and increasing resistance to distraction by both external and internal stimuli, although evidence for the effectiveness of this approach is still inconclusive (for example, see Hogarty et al. 2004, Pilling et al. 2002). Difficulties maintaining goal-relevant information in working memory have been posited to contribute to the pervasive lack of motivation that characterizes schizophrenia, but at the same time, such motivational deficits can impede both accurate assessment of cognitive functioning and effective engagement in cognitive remediation tasks for many individuals with this disorder (Barch 2005b).

Memory and Representation

One of the most important cognitive abilities is the retention of information over time and the ability to retrieve information when it is necessary or appropriate. Memory is important both because it allows experiences from the past to be reinstated and relived and because it allows people to use concepts gained over time to categorize and understand events and solve problems (Jonides 1995). Disorders involving loss of memory, such as Alzheimer’s and other forms of dementia, are both increasingly common and devastating in their costs to individuals, families, and society. Specific difficulties involving the organization and retrieval of memories are also being investigated in a variety of other disorders.

Memory can be broadly divided into “explicit” (or “declarative”) memory—which can be described, such as recalling a recent birthday party or knowing the year the French revolution occurred—and “implicit” (or “nondeclarative”) memory—which cannot be described but nonetheless affects future behavior and perception, for example a well-learned skill or a classically conditioned response. The formation, retrieval, and effects of each type of memory will be discussed in turn. In discussing memory generally, two points that will appear frequently are worth mentioning.

First, memory depends on representations, or the specific neural and cognitive states that correspond to an object or event in the world. These representations are not abstract but rather depend on and cause reinstatement of sensory and motor states specific to that object or event. In other words, both behavioral and neuroimaging work increasingly suggest that thinking about or remembering a recent birthday party with friends involves literally “re-living” that experience, with much of its perceptual, cognitive, and emotional details intact (Barsalou et al. 2003, Pecher et al. 2004).

Second, the formation of long-term memories is at least partially dissociable from processes of attention and working memory (Cave and Squire 1992). Indeed, often implicit memory is gained in the absence of attention, as often occurs during the priming of behavior with apparently incidental cues (Gabrieli et al. 1993, Postle et al. 1996, Schacter and Buckner 1998). Yet the aspects of a representation that are attended to are more likely to be encoded in long-term memory. This suggests that long-term memory is partially independent of executive processes, attention, and working memory (again suggesting modularity of these processes) but, nonetheless, interacts with all of these functions in encoding specific details of events. Hence, attentional biases in psychiatric disorders could contribute to distortions of memory seen in patient populations.

Explicit Memory

How do people remember their last birthday party, where they put their keys, or when they first rode a bicycle? While many people experience memory as working passively, like a camera recording and then replaying events, behavioral and neuroscientific research suggest that both encoding (the formation of memories) and retrieval are active processes. While a more active reconstruction is more adaptive than passive replaying of events in many ways, it also explains the retrieval of false memories, as caused by source misattribution and misinformation effects (Loftus and Hoffman 1989, Roediger and McDermott 1995).

Encoding

Several factors are known to affect the ways memories are encoded, and most of these have been studied by examining aspects of encoding that predict later success at retrieval. Three major findings in this area are especially worth mentioning: (1) attention, (2) level of processing, (3) the match between encoding and retrieval on variables such as processing level, context, and mood. We will discuss these processes in turn, along with the brain regions underlying them (see also Figure 26–2 and Table 26–2).

First, as mentioned above, attention is important to successful encoding, and information that is ignored is less likely to be well remembered. This effect is most often seen during divided attention tasks: when participants are asked to remember a list of words while concurrently performing a demanding task encoding success suffers (Craik et al. 1996). Furthermore, a key brain area commonly found to be active during encoding, the inferior frontal gyrus, is also central to working memory maintenance and is inhibited when participants encode information while performing a secondary task (Uncapher and Rugg 2005). The role of attention in encoding is intuitive to anyone who has ever forgotten where he/she placed their keys while thinking intently about something else. However, while attention is an important aspect of encoding, it is neither necessary nor sufficient for successful memory formation.

It is not only attention but also the specific object of one’s attention that predicts strong memory formation. That is, attending to meaningful information will serve memory more than attending to superficial information—a phenomenon known as level of processing (Craik and Lockhart 1972). In a classic demonstration of this effect, Craik and Tulving (1975) asked participants to make three types of decisions about a list of words: whether they were printed in upper or lower case letters (shallow encoding), whether they rhymed with another target word (intermediate encoding), or whether they belonged to a particular semantic category. Memory increased linearly as a function of the depth with which words were encoded. More recent work has shown that deep encoding of word lists activates the inferior frontal gyrus (Kapur et al. 1994), which predicts more successful encoding of both verbal and visuospatial information (Brewer et al. 1998, Wagner et al. 1998).

Finally, level of processing probably does not entirely explain successful retrieval because it does not take into account the level of processing at which an event must later be retrieved. For example, children studying for a national spelling bee may benefit more from intently studying the stems and silent letters in each word than by understanding their meanings. Memory in such cases is best served not by deep encoding, but by encoding that matches the level of retrieval needed for the task (Morris et al. 1977). Other related theories suggest that beyond the way that material is encoded, matching the internal and external contexts of encoding and retrieval also improves memory. For example, material learned underwater is better remembered when under water (Godden and Baddeley 1975), and material learned under the influence of marijuana is better remembered when also under the influence (but being under the influence worsens retrieval overall; Eich et al. 1975).

Matching of mood states at encoding and retrieval also improves recall. That is, events or stimuli encoded when in a positive or negative mood state are better retrieved under similar moods (Blaney 1986, Bower 1981). Speculation that this effect reflects the greater accessibility of mood-congruent memories when in a similar state is supported by neuroimaging data (Lewis and Critchley 2003, Lewis et al. 2005). Such accessibility effects are prevalent in psychiatric disorder, as for example in depressed individuals, who have a bias toward recalling negatively valenced experiences (Lloyd and Lishman 1975) and also show abnormal neural activity while recalling sad experiences (Elliott et al. 2002). Relating these biases to general memory and attention processes, we can speculate that they involve both a bias toward attending to negative cues during encoding and a heightened accessibility of negative memories due to negative mood at retrieval.

Binding and Retrieval

Similar to encoding, explicit retrieval is an active process, involving reconstruction of the details and experiences accompanying a memory. (Because it is most relevant to clinical disorders, we will concentrate on the retrieval of episodic memories, explicit memories of specific past events.)
Before a memory can be retrieved, however, it must be stored as a coherent representation by the brain. In other words, dissociated memories of candles, friends, kazoos, and fears of getting old are not enough to comprise a full memory of a past experience. These memories must instead be bound together, a process that occurs in the medial temporal lobe, in a structure called the hippocampus (Eldridge et al. 2000).

During binding, the sensory, cognitive, and affective components and context of an experience (together known as the signature of a memory, or an “engram”; see Schacter 1997) are associated with each other. Importantly, these components are not stored as abstract concepts, but rather as traces of the actual state experienced at encoding. Thus, encoding a sound recruits brain regions involved in audition, and retrieval of that sound’s memory reactivates part of that same sensory cortex; the same is true for visual memory (Wheeler et al. 2000). Similarly, brain areas related to taste become active when participants look at pictures of food (Simmonset al. 2005), and brain areas controlling motor function become engaged by looking at pictures of manipulable objects (Chao and Martin 2000).

These findings underscore the concept that retrieval of explicit memories depends on modality-specific representations (Martin and Chao 2001) and involves “reliving” sensory and motor aspects of past events. Later, recalling or being confronted with a single sensory component of an episode (a cue) can lead to pattern completion, in which related traces from the episode are retrieved and activated together, as a function of the hippocampus (McClelland et al. 1997). As such, a single cue can often bring back the rest of a memory automatically. This is especially relevant to individuals suffering from posttraumatic stress disorder, who experience flashbulb memories (or flashbacks) during which they are unable to stop a flood of sensory information related to their traumatic experiences.

Neural Mechanisms of Emotional Influences on Explicit Memory

The hippocampus, the brain region most directly responsible for binding and (with the inferior frontal gyrus) episodic encoding, is part of the medial temporal lobe. Adjacent to it is the amygdala, a brain region classically associated with negative emotions and more recently with high arousal and the maintenance of vigilance under threat (Davis and Whalen 2001, LeDoux 2000). The close spatial proximity between these regions is reflected in the strong and prevalent effects that emotion and arousal can have on memory. For example, participants shown emotional pictures later remember only emotional details of those pictures, forgetting nonemotional details, and this effect is mediated by their level of physiological arousal upon encountering the emotional stimuli (Cahill et al. 1994). Arousal leads to improved memory under attentional load (Kensinger and Corkin 2004), and even in amnesia (Hamann et al. 1997), suggesting that emotional memories may take a “different route” to being encoded than nonemotional ones, one fundamentally dependent on the amygdala (Anderson and Phelps 2001, Sharot et al. 2004). Enhancement of memory for valenced but nonarousing events may be supported by connections between the amygdala and the hippocampus (LaBar and Cabeza 2006). Again, individuals with posttraumatic stress disorder demonstrate abnormal activation of affect-related brain circuitry during symptom provocation (Rauch et al. 1996, Shin et al. 1997), suggesting neural mechanisms through which memories of trauma can come to dominate their mental lives.

Implicit Memory

Implicit memory includes any processing of stimuli that cannot be recalled consciously but, nonetheless, affects behavior. Implicit memory is both behaviorally and neurally distinct from explicit memory, providing another example of the modularity of cognition. For example, individuals with a complete inability to encode explicit memories as a result of hippocampal damage can nonetheless learn skills (Corkin 2002), express preferences and cognitive dissonance reduction (Lieberman et al. 2001), and learn classically conditioned associations (Bechara et al. 1995).

Priming

One of the most common examples of implicit memory is priming: the increased accessibility of a percept or concept after it is encountered, even without conscious awareness. For example, participants subliminally presented with words on a screen (e.g., “cat”) will not be able to explicitly recall any of these words. However, when asked to complete a word stem including letters from a briefly presented word (e.g., “ca_”), they will most often complete it with the primed word instead of with other possibilities. This phenomenon is known as perceptual priming, because the perceptual features of a stimulus are made accessible through priming without awareness that the stimulus has been presented. Conceptual priming, a closely related effect, occurs when the semantic content and associates of a primed stimulus are made accessible. For example, after seeing the word “cat” subliminally, participants will be faster at making decisions about whether a cat is an animal than after being primed with unrelated words or nonwords (for review, see Roediger 1990).

Social and Affective Priming

Interestingly, priming can also affect social and emotional behavior and concept accessibility. For example, participants shown negative words subliminally will be faster at making judgments about other negative words (Murphy and Zajonc 1993). Similarly, participants completing word stems describing personality traits will be more likely to unwittingly ascribe those traits to someone who is described to them (Higgins et al. 1977) and to act in ways congruent with that trait (Bargh et al. 1996). A similar process can be seen as accounting for the phenomenon known as transference (e.g., Freud 1912/1963). That is, subtle cues from a therapist or another person in an individual’s current environment can remind the individual of someone significant in his/her past and lead the mental representation of this previous other to become activated. When this happens, and it may do so without the individual even realizing it, information stored in the representation of the past other comes to influence the inferences, memories, emotions, motivations, and self-perceptions the person experiences in the present moment. Numerous studies of the transference process as defined in these cognitive terms have demonstrated profound effects of past others on our responses to new people in our lives (see Andersen and Chen 2002 for a review).
Abnormalities of Memory in Psychiatric Disorders

Empirical studies over the last two decades have demonstrated significant deficits in recognition and recall among clinically and subclinically depressed individuals. Generally, memory performance is most consistently impaired for explicit (consciously directed) memory (e.g., Brand et al. 1992, Colby and Gotlib 1988, Danion et al. 1991, Elliott and Greene 1992, Sweeny et al. 1989, Watts and Sharrock 1987). With respect to implicit memory, the evidence of memory deficits in depression is inconsistent and may depend on the particular task used to assess it (Jenkins and McDowall 2001). However, the research does clearly demonstrate that a mood-congruent memory bias (see Matt et al. 1992 for a review) leads to more negativistic recall among individuals with depression, as is consistent with Beck’s cognitive theory of the disorder (Beck 1976). Overall, relative to control subjects, individuals with depression or dysphoric mood display enhanced memory for negative autobiographical memories and experimentally presented stimuli, but they show poorer memory for positively toned memories and stimuli. In addition, both currently and formerly depressed individuals have difficulty retrieving specific memories of events from their own lives (Mackinger et al. 2000, Wessel et al. 2001). Such overgeneral autobiographical memory has also been associated with depressive rumination (e.g., Watkins and Teasdale 2000) and may well result from the depressed person’s repeated analysis of current or past difficulties in an attempt to make sense of them.

Memory deficits and overgeneral autobiographical memories are also characteristic of individuals with posttraumatic stress disorder (McNally et al. 1995). On standard memory tests these individuals show proactive interference, an impairment in the ability to encode and retrieve new information (e.g., Brenner et al. 1993, Sutker et al. 1993). Moreover, similar to what occurs in individuals with depression, the severity of current posttraumatic stress symptoms biases the content of stimuli and personal memories that are recalled. In several studies, individuals with posttraumatic stress disorder, who were currently highly symptomatic, recalled having experienced a greater number of traumatic events that they had not mentioned during a prior interview (Southwick et al. 1997). This finding highlights that memories are not singular or permanent but reconstructed anew from encoded elements throughout the brain whenever they are recalled. Hence, memories are subject to change over time and influenced by current factors including current clinical state.

Source misattribution is another clinically relevant memory difficulty in which people are able to recall an event but identify its source incorrectly; they cannot always reliably distinguish events that happened to them from events they have imagined, dreamed about, or heard about as having happened to someone else. This phenomenon may potentially contribute to false memory, and highly suggestive people as well as those with vivid imaginations appear to be more susceptible to it. Source misattribution is beginning to be considered in relation to dissociative disorders and some personality disorders, including borderline, narcissistic, and histrionic. In addition, there has been speculation that hallucinations and delusions in schizophrenia may involve source misattribution: internally generated thoughts may be misattributed to external sources, moreover, physiological responses to expected threats may be misinterpreted as responses to threats present in external reality (Beck and Rector 2005).

Evidence is also emerging that people vulnerable to social threat may organize information differently in memory from more secure individuals. Specifically, when people judge the attributes of a person they know in a timed judgment task, low self-esteem leads negative or positive cues to heighten accessibility of similarly valenced attributes of the person, but this effect does not occur when people judge the attributes of inanimate objects (Graham and Clark 2006). The tendency to organize interpersonal knowledge in memory by valence may develop to facilitate processing of threat in individuals who have been sensitized to it, but as a result, any negativity on the part of a close other tends to trigger a cascade of negative, threat-consistent associations that erode relationship stability (Murray and Holmes 1994, 1999, Graham and Clark 2006). At its extreme, this pattern resembles the idealization/devaluation criterion of borderline personality disorder, sometimes referred to as splitting (Fairbairn 1954, Kernberg 1976). Berenson and Downey (2007) found preliminary evidence for this pattern in the timed interpersonal judgments made by a small sample of people with borderline personality disorder relative to healthy controls.

Implications for Therapeutic Intervention

The fact that memories are continually reconstructed speaks directly to the need for caution regarding the accuracy of events reported during treatment, including the controversy over recovered memories of early traumatic events. Although traumatic events do really happen, the nature of memory makes the veracity of any particular memory of such an event impossible to discern. Likewise, there is the real possibility that false memories could arise in the course of treatment, as recall continues to be shaped by current influences (McNally 2003). But beyond these cautions, the nature of memory suggests that it may be usefully targeted for intervention. Specifically, reprocessing of troubling experiences in a new context appears to be beneficial in a wide range of treatment modalities, including narrative therapies, and various CBTs for trauma involving exposure to memories, thoughts, and feelings about the traumatic event in a context of relative safety (Foa et al. 2000).

Uniquely Social Cognition

Social cognition emerged as a field over the last 50 years, drawing upon theories and methods from both cognitive and social psychology (see also Chapter 27) to understand the ways that people form, maintain, and change their impressions of themselves and other people (for review, see Fiske and Taylor 1991). While many textbooks and reviews of cognitive psychology do not include discussions of social cognition, we feel it is worth doing so for two reasons. First, many psychiatric illnesses (such as autism, borderline personality disorder, antisocial personality disorder, and schizophrenia) are especially crippling in the social domain, affecting people’s abilities to accurately judge and adaptively interact with others (Baron-Cohen 1994, Bateman and Fonagy 2004, Blair 2005). Second, recent research in cognitive neuroscience confirms that
social cognition recruits brain areas not engaged during nonsocial cognition, suggesting that it is a modular process incorporating unique information-processing steps (Mitchell 2006).

The Uniqueness of Social Stimuli
Analyses of speech collected in natural settings demonstrate that over half of human conversation revolves around social topics (Dunbar 2004). Given the centrality of social stimuli, it makes sense that attention, memory, and other cognitive processes should have evolved to ably handle such information; however, this would not imply a necessity for unique mechanisms. After all, it is straightforward to assume that people attend to and remember others using the same processing steps and brain systems they would use to attend to and remember flashing checkerboards, or ferns, or player pianos. To be unique, social cognition must entail processes that differ qualitatively—in their cognitive and neural substrates—from those used for nonsocial stimuli, rather than being simply the application of generic cognitive processes to the social world.

One of the forces driving the recognition of social cognition as modular and dissociable from nonsocial cognition was the characterization of autism, a developmental illness that causes severe impairments in social cognition, often while sparing nonsocial cognitive abilities (especially in more mild forms of autism spectrum disorder; Baron-Cohen 1994). Autism also provides a picture of just how critical social cognition is to daily functioning: individuals with this disorder have severe problems understanding and behaving appropriately in social situations. Autism and related illnesses specifically affect the ability to see other people as intentional agents, with internal states such as thoughts, feelings, and goals, and it is in that one sense that people differ from all other stimuli. Indeed, most of us not only have the ability to perceive internal states, but also have a tendency to do so, even anthropomorphizing nonanimate objects when their movement could be construed as intentional (Heider and Simmel 1944). The tendency to perceive internal states is adaptive, because they are often the best predictor of behavior (Dennett 1987). Social cognition, which could be described as how people make sense of others and themselves, largely involves tuning into those internal states.

Recent neuroimaging studies provide the most convincing evidence that unique, modular processes underlie social cognition. In such studies, participants are asked to make judgments about the states or traits of either intentional agents such as people or nonintentional agents such as clothing, computers, or vegetables. Studies like these have revealed a set of brain regions, including the medial prefrontal cortex, posterior cingulate cortex, and superior temporal sulci, that are uniquely engaged in making inferences about intentional agents (Mitchell et al. 2002, 2005; see Figure 26–3 and Table 26–3). Furthermore, these brain areas are not engaged while thinking about people per se but rather respond selectively to imagining the internal mental or emotional states of intentional agents (Fletcher et al. 1995, Goel et al. 1995, Hynes et al. 2006, Ochsner et al. 2004a, Saxe and Kanwisher 2003), and even to the apparent intentional states of inanimate objects (Castelli et al. 2000). Finally, these brain regions are underactive in individuals with autism, both chronically and when attending to intentions (Castelli et al. 2002, Kennedy et al. 2006). Together, these data support a view of social cognition as modular and unique.

Cognitive Processes in Social Interaction
Effective interaction with others in the real world requires a combination of social and nonsocial cognition. Perceivers must integrate many types of information to correctly identify the internal states of others and the correct ways to respond to these states. In order to accomplish this processing, many systems, including working memory, long-term memory, attention, emotion, and social cognition, are simultaneously necessary. Downey et al. (in press) described three factors that allow for successful social interactions: (1) empathy, (2) cognitive perspective taking, (3) motivation. We will briefly discuss each of these factors, because they may be uniquely affected in different psychiatric illnesses.

(1) **Empathy**: It is difficult to watch someone get kicked in the shins without wincing, and this automatic reactivity to others has often been thought of as a precursor to empathy (Preston and de Waal 2002) and prosocial behavior (Batson et al. 2003). An often-cited factor in empathy that has been termed *shared representations* refers to a perceiver’s tendency to “put themselves in the place” of someone else and as such simulate for themselves what that other person could be feeling (Gallese 2003, Smith 1790/2002). More recently, a neural mechanism for shared representations has been found in the domain of *motor cognition* (Blakemore and Decety 2001). That is, thinking of executing an action engages the motor regions of the brain involved in actually performing it (Decety et al. 1994, Jeannerod and Decety 1995), and observing or simulating the actions of other people engages similar motor regions (Ruby and Decety 2001). Such work dovetails with the discovery, in nonhuman primates, of *mirror neurons* that fire both when monkeys perform an action and when they see another monkey performing it and are often invoked as the source of shared representations (Rizzolatti and Craighero 2004, Rizzolatti et al. 1999, 2001).

There is evidence that shared representations accompany the perception not only of actions but also of other people’s sensations, such as pain (Botvinick et al. 2005, Singer et al. 2004), disgust (Wicker et al. 2003), and touch (Keysers et al. 2004). Such studies have also demonstrated that brain regions responding to emotional experience (such as the anterior cingulate, anterior insula, and amygdala, see Figure 26–3) can be engaged by witnessing physical states and emotions in others (Carr et al. 2003, Decety and Jackson 2004, 2006). More evidence for such vicarious emotion underlying empathy has come from psychophysiological studies of observational fear learning, demonstrating that watching someone else receive shocks can create arousal and conditioned fear responses in an observer (Olsson and Phelps 2004). Such results have led to theories that social cognition and empathy consist mainly in these shared representations, which allow an observer to “translate” the bodily states of a social target into an experience they can share. However, there is little evidence that complex internal states could be understood by simple imitation; furthermore, the brain regions involved in simulating sensation and action are separate from those involved in perceiving intentional states. It is more likely that shared representations are one of a few important facets of cognition necessary for understanding others. The integration of empathy with more “top-down” social cognitive components described below may take place in association cortex, such as the medial and orbitofrontal cortex, which have been shown to be engaged during emotion recognition tasks (Vollm et al. 2006), and become functionally connected to the anterior cingulate and anterior insula when subjects watch others in pain (Zaki et al. 2007).

(2) **Cognitive perspective taking**: Perspective taking (also known as “theory of mind”) is the ability to understand the point of view of another person, even when that point of view diverges from one’s own. For example, the *false belief task* is a classic assessment of perspective taking in which participants are presented with the story of a character with a mistaken mental state and then asked to infer what the character’s mistaken mental state is (e.g., “Sally places a ball inside toy box A, but while she turns her back Anne moves it to toy box B. Where will Sally look for the ball?”). Unlike shared representations, perspective taking does not occur automatically and requires effort and attention on the part of the perceiver. Indeed, when under attentional load, people often fail to make the correct inferences about other people’s mental states (Gilbert et al. 1989). Working memory may also be critical to perspective taking in false belief tasks, because participants are required to maintain multiple perspectives in mind at once and inhibit their own knowledge while making inferences about others’ false beliefs. Support for this idea comes from developmental work showing that theory of mind improves in parallel with the development of executive functions (Carlson and Moses 2001).

(3) **Motivation**: While motivation is not uniquely social, it is an important ingredient of successful social cognition and may be affected in disorders that include altered social information processing. For example, information that can be threatening to a close relationship is often actively ignored (Simpson et al. 1995), yet people high in the need to belong, or those who have just experienced rejection, instead prioritize the detection of potential threat in social cues (Pickett et al. 2004). Motivations may be important in explaining social-cognitive biases in various emotional disorders, such as heightened responsiveness to potential threat in anxious individuals, and dejected withdrawal among those who readily interpret social cues as confirmation of their negative self-image. Finally, because it is in the context of social bonds that essential social-cognitive skills are honed with corrective feedback and practice, a lack of social motivation that isolates people from emotionally trusting relationships (in autism, schizophrenia, or schizoid personality disorder, for example) may contribute to pervasive difficulties understanding and effectively interacting with others.
Social Cognitive Difficulties in Psychiatric Disorders

Emotional Empathy in Psychopathy
In a recent review of empathy, Blair (2005) argued that while autism is associated with deficits in cognitive perspective taking (see below), it is less consistently associated with abnormalities in empathic emotional responding. The opposite is true of psychopathy: while psychopathic individuals do not consistently demonstrate difficulty in recognizing the emotions of others (Kosson et al. 2002, Richell et al. 2003), they show an attenuation or absence in their response to others’ emotions or pain. Abnormalities of emotional empathy in psychopathy have been demonstrated through multiple experimental paradigms, for example psychopathic individuals show a lack of vicarious conditioning toward pain in others (Aniskiewicz 1979). Furthermore, neuroimaging investigations of psychopathy indicate structural and functional deficits in both basic and social emotion processing that may underlie a lack of remorse for antisocial acts. For example, psychopathic individuals show a volumetric decrease in the orbitofrontal cortex, which is associated with the extent of their violent criminal behavior (Raine et al. 2000). In recent functional imaging investigations, psychopathic criminals showed less activation in the amygdala during an emotional memory task (Kiehl et al. 2001) and less activation in the extrastriate visual cortex when observing emotional facial expressions (Deeley et al. 2006). All of these findings suggest that psychopathy may involve a generalized lack of reactivity to affective stimuli, which manifests itself in part as a failure in emotional empathy (Kiehl 2006).

Perspective Taking and Motivation in Autism and Schizophrenia
Human interactions require a continuously updated understanding of mental states, and indeed descriptions of mental states are central to a majority of conversation (Dunbar 2004). Profound difficulties understanding the mental states of others thus make individuals with autism cut off from and bewildered by a substantial part of the world around them (for a personal account of autism’s impact on social functioning, see Grandin 1996). The last 20 years has seen an increase in the study of autism and its related social-cognitive impairments, using both cognitive and neuroimaging methodologies. The resulting work suggests that autism spectrum disorder may have multiple effects on the social-cognitive axes described above. For example, impairments of cognitive perspective taking in autism, which are well documented by routine failures on the false belief task described previously (Leslie 1994), map onto failures to activate related brain regions such as the medial prefrontal cortex (Baron-Cohen et al. 1999, Castelli et al. 2002, Happe et al. 1996). Individuals with autism have also been shown to have deficits in the mirror-neuron system associated with shared motor representations (Dapretto et al. 2006, Hadjikhani et al. 2005). Although it has been posited to be at the root of social-cognitive deficits in autism (Oberman and Ramachandran 2007), mirror system dysfunction has not been conclusively tied to difficulties in motor empathy or understanding intentions in others. However, there is evidence that individuals with autism have difficulties identifying emotional facial expressions and that this may be tied to the way in which they process facial information. For example, they do not attend to other people’s eyes as a crucial social signal for nonautistic individuals (Pelphrey et al. 2002, Ristic et al. 2005). This abnormality in autism is shared by people with amygdala damage (Spezio et al. 2007a, 2007b), and there is emerging evidence that amygdala dysfunction may directly contribute to impaired deployment of attention to social cues in autism (Dalton et al. 2005). Thus, autism appears to involve both neural and cognitive abnormalities affecting multiple aspects of social cognition.

Difficulties of a social-cognitive nature have also been well documented in schizophrenia and are central predictors of social and vocational outcome among individuals with the disorder (e.g., Kee et al. 2003, Mueser et al. 1996). Some of the problems that arise for people with schizophrenia in social situations are related to their deficient regulation of attention, such that distracting thoughts intrude upon and disorganize their speech or leave few cognitive resources to spare for participating in conversation much at all (Melinder and Barch 2003). Nonspecific factors such as cognitive slowing and a pervasive lack of motivation may also contribute to social interaction difficulties (Barch 2005a). Yet other primary symptoms of schizophrenia can be conceptualized in explicitly social-cognitive terms. Delusions involve biased information processing in which percepts are overinterpreted as personally relevant and externally caused. In turn, hypervigilant attention to cues consistent with the delusion and poor self-correction of erroneous interpretations lead delusional ideas to be maintained and intensified over time (Beck and Rector 2005). However, with the exception of particular delusion-consistent cues, individuals with schizophrenia demonstrate poor utilization of cues from the social environment, including failure to concentrate visual attention on relevant features of faces or social contexts, and deficits in recognition of others’ facial affects and mental states in perspective-taking tasks (for a review, see Green et al. 2005). They have trouble understanding their own internal states as well and tend to interpret these states in terms of concrete factors external to their own mind (as when a self-critical thought is understood as a persecutory auditory hallucination; Beck and Rector 2005). Impaired cognitive understanding of social situations in schizophrenia hence appears to involve many factors, including perceptual difficulties, cognitive biases, a shortage of cognitive resources for examining and correcting delusional and hallucinatory explanations for experiences, and a lack of motivation to interact with others who might offer alternative explanations. Information-processing and neural mechanisms of schizophrenia symptomatology represent important areas for future investigation on the interface between social and nonsocial cognition.

Motivation and Interpretive Biases in Anxiety Disorders and Depression
Individuals with anxiety disorders and depression also show social-cognitive difficulties in that they interpret the world around them in characteristically distorted ways. Like people with schizophrenia, people with these disorders show a personalization bias, in that they accord environmental cues more significant for the self and the future than is really the case. For example, individuals with anxiety disorders often interpret ambiguous or benign stimuli as threats with which
he/she will be unable to cope, and depressed persons interpret these as evidence of being worthless and without hope for the future. As such, interpretational biases in these illnesses may relate to subsequently biased memory. However, unlike the externalizing attributions that occur in schizophrenia, attributions in anxiety disorders and depression typically involve assumptions of exaggerated personal vulnerability or deficiency, consistent with the affective states associated with these disorders.

Negative interpretive biases have been demonstrated in several types of experimental tasks assessing responses to ambiguous stimuli. The emotion identification task, for example, presents participants with images depicting emotional states in graded, computer-generated blends (e.g., of a neutral face with a sad face) and assesses the strength with which an emotional expression must be present for the participant to identify it. Another task asks participants to identify the meaning of words that are ambiguous in that they can be interpreted as having either negative or neutral content (e.g., “sink”). Research shows that individuals with social phobia are able to correctly identify angry facial expressions at lower intensity than control or depressed participants (Joormann and Gotlib 2006). A similar pattern involving a heightened detection, specifically of threatening expressions, has been shown among abused children (Pollak and Kistler 2002) and adults who are high in sensitivity to rejection (Ölsson and Downey 2007). Individuals with generalized anxiety disorder interpret ambiguous words with more threat-related meanings than do controls (Mogg et al. 2004a). Depressed individuals, compared to socially phobic individuals and controls, require a higher intensity of happiness to be present in a facial expression before they will correctly identify it as happy. Moreover, unlike the socially phobic, depressed individuals correctly identify sad faces at lower thresholds than angry faces (Joorman and Gotlib 2006). In another study, clinically depressed individuals interpreted ambiguous words as having more negative meanings and also recalled more negative words later, relative to controls (Mogg et al. 2006). Further evidence suggests that a negative bias in interpreting ambiguous stimuli can prospectively predict dysphoric reactions to stress (Pury 2002) and later depression diagnosis (Rude et al. 2003).

In spite of their contribution to mood states that are aversive and that impair ordinary functioning, the biased patterns of interpretation associated with anxiety disorders and depression make sense from a motivational standpoint. After all, it is more adaptive to perceive a safe situation as dangerous than to overlook a real danger by assuming that it is safe. Likewise, recognition of when pursuit of a goal will inevitably fail is functional, in that disengagement from the goal prevents wasting valuable resources (Oatley and Johnson-Laird 1987). In these disorders, however, inaccurate assumptions about the base rate of negative outcomes lead such self-protective motivations to be invoked more frequently than is warranted, with both current mood states and mood-congruent biases of attention and memory (previously discussed) perpetuating negatively biased interpretations. Viewing the self and others through such a negatively biased perspective can, in turn, lead to maladaptive behavior and negative social outcomes. Hence, the negative social-cognitive biases that occur in emotional disorders may be understood in terms of basic self-protective motivations gone awry.

Implications for Therapeutic Intervention

Cognitive therapy interventions address biases in expectations and interpretations by identifying, challenging, and modifying the distorted automatic thoughts and underlying beliefs (maladaptive assumptions and negative schemas) from which they arise (for examples of interventions, see Leahy and Holland 2000). To do this requires detailed information about the contexts in which symptoms occur, including perceptions of antecedent events, and the specific thoughts the individual had about them. For example, a depressed individual who felt particularly despondent after taking an examination may report preoccupation with examination questions he/she was unable to answer and thoughts in which assumptions are being made about what the missed questions mean about the self and the future (“I’m doing badly in this class,” “I’m stupid,” and “I’ll always be a failure”). Modifying depressogenic thoughts involves identifying the errors implicit in them and deliberately rehearsing less distorted counterstatements (“I also got a lot of questions right.” “I’ve gotten plenty of good grades so I can’t be stupid,” and “even if this grade isn’t my best it is just one class not my whole life”). After engaging in these exercises over time, the individual may also be able to identify basic maladaptive assumptions that repeatedly underlie his/her problematic thought patterns (“If I’m not perfect then I’m worthless”). The notion that a set of basic maladaptive assumptions about the self and others can underlie even quite pervasive psychiatric difficulties is the foundation for cognitive therapy for personality disorders (Young 1990). Thoughts that promote anxiety and panic (e.g., “this elevator will crash,” “everyone is noticing how anxious I am,” and “my heart is pounding so fast that I’ll die”) are also effectively modified with cognitive therapy. However, because avoidance and cognitively overwhelming anxious arousal are endemic to anxiety disorders, graded exposure exercises and training in relaxation techniques are typically used to ensure that the person is sufficiently exposed to and able to cope with the situations that elicit anxiogenic thoughts. Cognitive therapy has also been applied to modify the interpretive biases that make people with schizophrenia so convinced of their delusions and hallucinations. Framing these experiences in terms of thought patterns with particular contexts and antecedents, the therapist guides the person through examining the evidence for and against particular explanations for their experiences (Beck and Rector 2005).

The quality of the therapeutic relationship is universally important in all forms of treatment but is a particularly critical and challenging aspect of treatment of disorders where social-cognitive difficulties lead to low ability to trust others. For individuals with schizophrenia, establishing trust is no small therapeutic goal, given their motivational deficits and pervasive misinterpretation of others’ intentions. Yet without trust it would be impossible to engage the patient in revealing and challenging his/her assumptions about the world; hence, the first stage of cognitive therapy for schizophrenia is solely focused on the establishment of trust in the treatment relationship (Beck and Rector 2005). By contrast, for individuals with borderline personality disorder, mistrustful tendencies to misinterpret and overreact in social interactions are typi-
ally accompanied by strong motivation for the rewards of social connection. Hence, so long as it does not succumb to volatile interpersonal patterns, the therapeutic relationship can readily become a crucial leverage point for engaging the patient in the direction of change.

Various forms of social skills training also directly target social-cognitive difficulties that lead to volatile relationships and isolation, often through a combination of didactic instruction and practice. The skills-training sessions that are an integral part of dialectical behavior therapy for borderline personality disorder include material to address specific problem areas of social interaction. For example, sessions focusing on how to make or refuse a request specifically highlight the importance of cognitive perspective taking so that the level of firmness and persistence of interpersonal behavior be appropriate to the situation and the other person’s response (Linehan 1993).

Conclusions: Modularity and Integration

This chapter has focused on unpacking the workings of a few core cognitive processes and then examining possibilities of how these processes may be disrupted in psychiatric illness. We have presented topics such as attention, memory, and executive function as modular, discussing them independently of each other. Modularity is an important concept in cognitive neuroscience and psychology, in that it allows us to “carve nature at its joints” and understand the uniqueness of different processes in our mental toolkit. However, at another level, this modularity is simply descriptive. It is difficult to imagine executive function, for example, proceeding normally in the complete absence of long-term memory or representation. And nowhere is this clearer than in the study of psychiatric disorders, which often include deficits cutting across cognitive, social, and emotional domains. Indeed, to forge integrative cognitive models of mental illness, it is critical to understand the interactions between disparate cognitive functions. Luckily, this is precisely the direction that cognitive neuroscience has recently taken. When functional neuroimaging emerged about 20 years ago, the major aim of most researchers was to discover the loci of various cognitive processes. Now, however, just as much work goes into understanding the circuitry of brain areas responsible for interactions between cognitive and emotional systems using new theoretical models and analysis techniques. Neuroscience models of mental illness should follow suit, moving away from explaining single structural or functional abnormalities in cognitive and neural function and toward integrative views of both function and dysregulation.

Introduction
By training, interest, and definition as a medical specialty, the field of psychiatry emphasizes the medical treatment of psychopathology (illnesses or disorders) of individual patients (children and adults). Social psychology scientifically studies, often by experimentation, the way in which behaviors and cognitions of persons usually without pre-existing psychopathology are shaped by the social environment and influenced by the real or imagined presence of other people (Allport 1954). The social psychologist is not so much focused on individual differences, but rather in determining scientifically the general principles that determine how social influences affect the behaviors of all people. This chapter is not meant to cover exhaustively the implications of the social psychology literature for clinical psychiatry, and due to space limitations it is beyond the scope of this chapter to survey the vast field of social psychology.

In this chapter, we focus mainly on persons without major mental disorders, in order to illustrate to the reader some of the fundamental principles involved in interpersonal behavior, the formation of the “self” via feedback from other people, and some of the fundamental principles involved in interpersonal behavior. In the chapter 26, the authors describe the principles of normal cognitive processes, and illustrates how disordered cognitive processing can distort an individual’s ability to follow the “rules” of interpersonal functioning that are illustrated in this chapter, including the loss of ability to detect, interpret, and calculate the relative benefits and costs of chosen behaviors.

The loss of the ability to engage in the interpersonal dynamics that are described in this chapter is well known to all psychiatrists because it occurs in individuals with the major mental disorder of schizophrenia as well as other major disorders including the dementias. In schizophrenia, the person often loses or does not develop the cognitive skills (social cognition) that are required to understand the “rules” of social relationships (Burns 2006). Social cognition includes face perception, emotional processing, self-reference and working memory and a “theory of mind,” by which one assumes that another individual possesses a mind just like one’s own, so therefore one can attribute mental states to others and engage cognitively in the social arena (Grady and Keightley 2002).

Social cognition at a cellular level is thought to involve “mirror neurons” in Broca’s area, the premotor cortex, the superior temporal sulcus, and the posterior parietal cortex in humans (Rizzolatti et al. 1996, Decety and Grezes 1999, Buccino et al. 2004). Mirror neurons normally simulate actions that one sees another person do, and internally “represent” this action for us. As such, this system may provide the basis for shared human experience. If this cortical system is damaged as occurs in schizophrenia, interpersonal relatedness or “social cognition” is gravely impaired. This phenomenon will be described in more detail in the chapter 26. It has been argued that the sense of alienation often experienced by persons with schizophrenia, and the depression and “disembodiment” that they sometimes experience, are related to impairments in social cognition.

We will now describe some of the challenges that social systems present for all of us.
Attributional Style and Vulnerability to Depression

Social psychology’s attribution theory plays a central role in one of several cognitive vulnerability models of depression (Alloy et al. 1989). Attribution theory elucidates how people explain events and experiences in their lives, and the adaptational consequences of those explanations. The theory, developed by Heider (1958) and later elaborated by Jones and Davis (1965), Kelly (1967), and Weiner (1974), dominated social psychology during the 1970s. Attribution theory concerns itself with how individuals “attribute” or explain the behavior of other people, events, or their own behavior. Attribution theory proposes that people attribute a given behavior either to causes outside of the person or to some factor within the person who is performing the action (“dispositional” or “internal” factors). Responsibility for the behavior is assigned or not assigned depending on the attribution of the cause of the behavior. Factors that determine attribution include effect on self-esteem (i.e., one’s bad behavior is more likely to be attributed to outside causes than is one’s good behavior), universality of the behavior (everyone behaves in that manner, so it is just a habit or manifestation of conformity), and unusual nature of the particular behavior at a given time. Embedded in the concept of attribution is the assumption that individuals try to determine why others act as they do (Weiner 1974), and that these explanations for behavior occur after the fact.

The concept of locus of control (Rotter 1966) is grounded in expectancy-value theory, and is related to attribution theory but concerns expectation for future events, and what influences them. “Internal control” refers to the idea that the individual believes s/he can control a future outcome while “external control” refers to the belief that the outcome is outside of one’s control. Later revisions of the locus of control model, including that of Levenson (1973), proposed three dimensions: internality, chance, and powerful others. According to this model, a person can assess a proportion of control of an event to a combination of one or more of these factors simultaneously.

Around the same time as attribution theory was developed, coincidentally Seligman’s (1975) animal model of learned helplessness was proposed as a way to understand the development of depression. But by the late 1970s investigators and clinicians became increasingly disenchanted with the learned helplessness model. In response to numerous critiques, Abramson et al. (1978) offered a “reformulated learned helplessness model of depression.” Drawing on the success of attribution theory in explaining behavior, they learned helplessness model of depression. “Drawing on the critiques, Abramson et al. (1978) offered a “reformulated learned helplessness model. In response to numerous investigators and clinicians became increasingly disenchanted with the learned helplessness model. In response to numerous critiques, Abramson et al. (1978) offered a “reformulated learned helplessness model of depression.” Drawing on the success of attribution theory in explaining behavior, they argued that unlike an infrahuman, when a person experiences helplessness, she asks herself why she is helpless. According to the reformulated model, the answer to that question—a causal attribution or causal explanation—determines the breadth, depth, and duration of the individual’s depressive symptoms. If she explains her helplessness as due to a temporally stable factor, her symptoms will endure. Similarly, if she attributes her helplessness to a factor that will affect many life domains, that is, a global causal factor, her subsequent depression will manifest itself broadly in everyday life.

A later modification of the model, known as the hopelessness model of depression (Abramson et al. 1989), refers to people’s characteristic styles of explaining negative life events. Rather than focusing on explanations for specific encounters, the model postulates that people maintain an explanatory style. Individuals who characteristically believe that negative events are produced by stable and global causes are more likely to experience a depressive episode, especially after a stressful life event (Table 27–1).

As a cognitive vulnerability model, the hopelessness model of depression shares with Beck’s (1987) theory of depression the notion that certain ways of thinking about oneself and the world leave some people vulnerable to depression. In Beck’s theory, the cognitive vulnerability involves believing that one’s worth is contingent on being perfect or on others’ approval, whereas in the hopelessness model the vulnerability is the inclination to make stable and global causal attributions for negative life encounters. Although the hopelessness model hypothesizes that individuals vulnerable to depression also “catastrophize” about negative events and tend to infer from these events that they are personally flawed, we focus here on the model’s attributional component.

Until recently, most studies providing support for the hypothesis that a “depressive attributional style” is a cognitive vulnerability for depression had examined attributional style as a predictor of subsequent depressive symptoms rather than the onset on a major depressive episode. But findings from the Temple-Wisconsin Cognitive Vulnerability to Depression Project (CVD; Alloy et al. 2000) demonstrate that people’s inferential styles, which include their interpretation of the causes, consequences, and self-relevant implications of negative life encounters, predict the onset of major depressive episodes among individuals who have never before been depressed, and recurrence among those who have previously experienced a depressive episode. These findings are most relevant to clinical psychiatry.

Haefeli et al. (2005) distinguish two strategies that have been used to test cognitive vulnerability models, including the attributional component of the hopelessness model. The more widely used approach is the remitted depression paradigm (Just et al. 2001), in which the cognitive tendencies of individuals with a lifetime history of depression in full remission are compared to the tendencies of a never depressed comparison group. The second strategy, found in more recent tests of cognitive vulnerability models, involves a behavioral high-risk design, in which nondepressed individuals considered to be at high or low risk for depression based on their cognitive tendencies are followed over years to determine whether the high-risk group, for example participants with a depressive attributional style, is more likely to experience a subsequent episode of major depression.
The CVD study began by recruiting from two universities a large sample of nondepressed college freshmen with no other mental disorders. These students were identified as being at high or low risk for depression based in part on their attributional styles. They completed a structured diagnostic interview, and were followed every 6 weeks for 2.5 years and then every 4 months for another 3 years. Among these young adults who were not currently depressed but had a lifetime history of depression, those deemed as high risk for depression based on their attributional style were more likely than their low-risk counterparts to develop a depression recurrence during the course of the study (27% vs. 6%). Similarly, among study participants with no prior depression history, those at high risk were more likely than their low-risk counterparts to develop a first onset major depression (17% vs. 1%; see Alloy et al. 1999). Thus, attributional style predicted prospectively both first onset depression and recurrence. Using a different large sample of college students and a remitted depression design, Haefeli et al. (2005) found that young adults who had experienced their last major depressive episode on average more than a year prior to study participation showed a stronger tendency than their never depressed peers to endorse stable and global causal explanations for negative life events, even after controlling for current levels of depressive symptoms. Most recently, Alloy et al. (2006) found that the prospective link between depressive attributional style and subsequent depression was specific to depressive disorders; although cognitively high-risk young adults in the CVD sample were indeed at risk for subsequent first onset depression or recurrence, they were not more likely to experience the onset of an anxiety or other Axis I disorder.

Overall, there is now converging evidence that the social psychological construct of attributional style distinguishes never depressed from previously depressed individuals, predicts first onset depressions as well as recurrences, and appears to be specific to depression. Evidence suggesting that cognitive therapy for depression reduces relapse rates at least in part by decreasing patients’ tendencies to make stable and global explanations for negative events (DeRubeis and Hollon 1995), and that preventive interventions designed to interfere with a depressive explanatory style appear to protect against subsequent depressive symptoms (Gillham et al. 1995), underscore the clinical and public health implications of attributional style and the potential clinical utility of attribution theory for psychiatric practice.

Although proponents of cognitive vulnerability models have been careful to distinguish (presumably modifiable) cognitive vulnerabilities from (immutable) genetic or biological traits (Just et al. 2001), we encourage psychiatric investigators and clinicians to pay greater attention to possible links between genetic and cognitive vulnerabilities to depression and other mental disorders. We can imagine, for example, that a polymorphism in the serotonin transporter gene may leave affected individuals vulnerable to biased information processing, including biased attributional tendencies. But even if genetic and cognitive vulnerabilities do not ultimately unfold in a mediated fashion, they may have additive or synergistic effects that would have important etiologic, preventive, diagnostic, and treatment implications.

Finding Benefits and Experiencing Growth through Adversity

The positive illusions framework and the concept of benefit-finding were derived in part from the social psychology theories concerning attribution and locus of control. It has become almost axiomatic in the psychiatric literature to consider contact with reality a key feature of emotional health (e.g., Jahoda 1958). Yet more than two decades of social psychological investigation indicates that mild positive illusions, that is, positively skewed reality distortions especially among physically ill persons, may underlie positive mental health and recovery from physical illness (Taylor and Brown 1988, Taylor et al. 2000). Although there has been some debate in the literature regarding the emotional and physical health advantages of positive illusions (e.g., Colvin and Block 1994), and the findings are not yet conclusive, a growing body of social psychological literature points to the potential benefits of positive illusions (Table 27–2).

We focus here on one aspect of this area of investigation: Finding benefits and experiencing growth in the face of adversity. The traditional psychiatric literature has understandably focused on the negative emotional consequences of trauma, adversity, and serious illness. And indeed, this traditional perspective has advanced our understanding of phenomena such as posttraumatic stress disorder (PTSD). Yet this focus on the negative sequelae of adversity has led clinicians to interpret patient reports of benefits or personal growth following serious illness or loss as an indicator of denial, avoidance, or maladaptive wishful thinking.

The empirical literature paints a far more nuanced and provocatively hopeful picture. More than 300 empirical investigations and theoretical formulations have now been published in the area of benefit-finding and growth following adversity (Lechner et al., in press). People regularly report growth or benefits in the form of enhanced relations with others, positive personal change such as gained wisdom and strength, and changes in life philosophy. To be sure, the association between benefit-finding and positive adjustment has yielded some inconsistent results (see Linley and Joseph 2004, Stanton et al. 2006, Zoellner and Maercker 2006 for reviews). Nonetheless, several of the better designed studies with longitudinal predictions suggest that benefit-finding, rather than being an indicator of maladaptive wishful thinking, can be an adaptive resource. We now review these studies briefly, which were originally reviewed by Tennen and Affleck (2002).

As part of a study of adjustment to bereavement, Davis et al. (1998) interviewed people who had 6 months earlier lost a parent, spouse, partner, child, or sibling, and who had been followed since their loved one had been in hospice care. These bereaved individuals were asked if they had found
anything positive in the loss. Seventy-three percent endorsed some benefits. Davis et al. (1998) found that benefit-finding 6 months after the loss predicted distress levels 7 months later, even after controlling for both distress during the loved one’s hospice care and the extent to which the loss “made sense” to the participant.

In a study of mothers whose infants were in neonatal intensive care, Affleck and Tennen (1991) asked these mothers whether they had found any benefits from their child’s hazardous delivery and hospitalization. Three-fourths of the study participants endorsed at least one benefit. Benefit-finding predicted not only mothers’ own well being, but also her child’s developmental test scores 18 months later, even after controlling for the severity of the infant’s perinatal medical problems. These findings should interest infant and child psychiatrists and consultation liaison psychiatrists.

In another study that should interest consultation liaison psychiatrists, Affleck et al. (1987) asked a large sample of men, who had seven weeks earlier survived their first heart attack, whether they experienced any benefits or gains from the heart attack. Eight years later, those men who had reported at least one benefit were in better cardiac health and were less likely to have suffered another attack over the subsequent 8 years. These findings controlled for the severity of the first attack.

Psychiatrists have become increasingly familiar with the negative consequences of traumatic encounters, particularly PTSD. In a study of people who experienced one of three disasters involving extensive property damage and loss of life—a severe tornado, a plane crashing into a hotel lobby, or a mass shooting—McMillen et al. (1997) interviewed survivors 4 to 6 weeks after the incident and again 3 years later. Through a structured diagnostic interview, they assessed lifetime mental disorders. Individuals who reported benefits soon after experiencing the disaster were less likely to meet criteria for PTSD 3 years later. This prospective relationship is remarkable because it controlled for injury during the disaster, gender, and the number of preincident psychiatric diagnoses, each of which made a unique contribution to the longitudinal prediction of PTSD.

As the prognosis for HIV+ individuals has improved, psychiatrists have had the opportunity to become more involved in their long-term care. Bower et al. (1998) interviewed bereaved HIV-seropositive men on average 8 months after they had lost a close friend or partner to AIDS. Every 6 months they were examined for AIDS’ signs and symptoms, and were interviewed regarding their health behaviors. Benefit-finding predicted subsequent CD4 T lymphocyte decline and a lower rate of AIDS-related mortality over the next 4 to 9 years, and neither of these associations was mediated by health behaviors. On the other hand, the prospective relationship between benefit-finding and mortality was fully mediated by a less rapid decline in CD4 lymphocytes. Finally, psychiatrists are called upon frequently to assist chronic pain patients cope more effectively with their pain. Tennen et al. (1992) assessed benefit-finding among rheumatoid arthritis (RA) patients before the patients completed and submitted in the next day’s mail a diary of their daily pain, mood, and pain-related activity limitations each evening for 75 days. Perceived benefits at the start of the study moderated the relationship between pain severity and activity limitations. In other words, with increased levels of daily pain, RA patients who had endorsed more benefits reported fewer days during which their activities were limited by that day’s pain (Table 27–3).

Social psychology’s positive illusions framework has fueled keen interest in benefit-finding and perceived growth in the face of adversity and trauma. The theoretical and empirical literature in this area is beginning to change the way some mental health clinicians conceptualize people’s responses to traumatic encounters. Indeed, this line of inquiry holds the potential to influence more generally our understanding of stress reactions and may offer clues to new therapeutic approaches. Yet the study of benefit-finding and posttraumatic growth is based almost completely on people’s retrospective reports of personal change over time. Within social psychology there is a convincing body of evidence demonstrating the limits of personal autobiographical memory, including evidence that people are unreliable in reporting personal change (see Tennen and Affleck, in press, for a review). Although new methodologies offer the promise of detecting personal change more reliably, a widely used tool in clinical psychiatry—the depression rating scale—continues to rely on patients’ recalled experience and changes in experience. We now turn to depression rating scales and to what social psychological research might contribute to how psychiatrists assess depression based on patient self-reports.

### Table 27–3 How Benefit-Finding Can Enhance Interpersonal Growth Following Adversity

- Enhanced relations with others
- Positive personal change (wisdom, strength)
- Change in life philosophy

**Self-Report Depression Rating Scales: A Social Psychological Perspective**

Depression may be the most frequently studied phenomenon in psychiatry, and it is surely the most common disorder seen in general psychiatric practice. Depression severity scales completed by the patient, as well as those completed by the psychiatrist but based largely on the patient’s report, have become a mainstay of psychiatric practice and research. These scales require patients to recall their symptoms, typically over several days to a few weeks. The ease with which patients complete these scales has been interpreted as a reflection of the accuracy of their recollections. However, an impressive literature at the interface of social and cognitive psychology, reviewed recently by Tennen (2006), suggests that such symptom reports are almost surely fraught with recall decay and systematic bias.

All depression rating scales ask patients to recall their sadness, guilt, sleep quality, and other depressive symptoms over the previous few days to 2 weeks. Yet evidence from the social psychology literature indicates that when asked to recall recent emotional experiences, people actually reconstruct that experience based on an implicit theory of change and a variety of cognitive heuristics (Kahneman 1999, Ross and Wilson 2003). When patients attempt to recall their mood during the past week or 2, they most likely retrieve particular moments, that is, episodic memory, from that time frame. Because episodic memory fades rapidly, patients completing a depression rating scale may also draw upon their beliefs about their moods.
People provide different answers depending upon whether mood is reported in real time or retrospectively (Robinson and Clore 2002). Depressive symptoms recalled over just a few days can also be influenced by the most intense experience during that time, by the most recent experience, or by the individual’s emotional state when completing the depression measure (Stone et al. 1999). The social psychological literature indicates that these reporting inaccuracies are not simply random error, but rather systematic bias in recalled emotional symptoms. Retrospections over time periods longer than a week, commonly required in depression measures and structured clinical interviews, show increasing levels of bias as people begin to draw on their beliefs about their mood rather than reporting on their accurately recalled mood (Tugade et al. 2007).

Depression rating scales also require patients to average their experience over time. Such averaging has been shown to lead patients to rely on cognitive “shortcuts,” which are typically different from the average of recent emotional experiences as they were actually experienced (Robinson and Clore 2002), and different from the experiences clinical investigators and psychiatric clinicians assume they are capturing in depression rating scales. This empirically documented distinction between emotional experience as it unfolds in real time and recalled emotional experience also suggests that for a pharmacological or psychotherapeutic treatment to be found effective, the treatment would need to change not only experience itself, but the recollection of that experience as measured by depression scales (Moskowitz and Young 2006).

Some items on depression rating scales require patients to estimate recent symptom changes, such as worrying more than usual, or being more irritated than usual. The social psychological literature, however, tells us that people are even less accurate when reporting symptom changes than when reporting recollected symptoms because such judgments require recalling oneself at two different times and then making a comparison (Ross and Wilson 2003). Stone (2005) has demonstrated how reports of symptom change may not reflect actual change.

Most depression rating scales also ask patients to recall how their own responses covaried with changes in everyday life situations. For example, these scales ask patients whether they felt more cheerful if something good happened, or whether they blamed themselves when they experienced a negative outcome. Again, the empirical literature at the interface of social and cognitive psychology reveals that a patient who expects a relationship between a particular change in her social environment and her behavior will overestimate the magnitude of any relation that might exist, or even infer a relation when none exists.

Paper diaries, electronic pagers, and palmtop computers can measure symptoms closer to their real-time occurrence. This approach has been called a daily process method (Tenneti et al. 2000), ecological momentary assessment (Stone et al. 1999), and experience sampling (Csikszentmihalyi and Larson 1987). Lenderking et al. (2004) showed that daily depression symptom assessments were more sensitive than traditional weekly assessments in detecting early response to antidepressant treatment. Kranzler et al. (2004) used daily symptom reports to examine the mechanisms of therapeutic action in a pharmacotherapy trial. And Gunthert et al. (2005) used daily reports to show that depressed patients who began cognitive therapy with a relatively less pronounced negative emotional response to everyday negative encounters showed greater reduction in depressive symptoms over the course of treatment (Table 27–4).

The Self
Psychiatry, social psychology, and cognitive psychology have one of their most intimate interfaces around the concept of the self. The literature on the self within the fields of psychiatry and cognitive psychology is covered elsewhere in this section (see chapter 28 and chapter 26). We touch on a few important points here to establish a foundation for integrating some of the contributions of social psychology with those of psychiatry.

Psychiatry has generally focused on the psychopathology of the individual and the pathology of the individual self, especially with respect to normal and abnormal development of the self in the context growth within the nuclear family. Freud (1957) believed that for infants and even for normal adults, psychological investment in the self remained more important than investment in other people. Later, psychoanalysts (Winnicott, Bowlby, and others) argued that the bond between mother and infant was primary or very important and existed from early infancy.

Melanie Klein and Otto Kernberg (Klein 1930, Kernberg 1975) observed that the interpersonal relationships within the family during a child’s development sometimes generated a complex world of internalized mental representations of these other persons (“objects”). Some patients who experience dysfunctional family relationships develop intense feelings of aggression and envy, and such patients, suffering from the self-disorder of narcissism, develop pathological mental processes, structures, and behaviors in an effort to compensate for these intense feelings. Kohut (1977) proposed that the self could develop only within the context of intrapsychic representations of other people (“self-objects”), and that self-object relationships established and maintained a cohesive sense of self, which was associated with an ongoing sense of positive self-regard and self-esteem. He believed that damage to the formation of the self resulted in the development of defensive and compensatory mental structures and behaviors to try to maintain self-esteem, and argued that an individual with a self-disorder was preoccupied with the experience of the damaged self. In general, maintaining self-esteem has been a prominent feature of most theories of the self that currently are described in the psychiatric literature.

The “Self” within Social Psychology
Social psychology studies the normal self within its ongoing broader interpersonal and social context, and often begins with a focus on cognitive elements and changes in cognition rather than a focus on emotion or affect. However, in the area of the “self” within social psychology, the more
affectively laden concept of self-esteem maintenance has become prominent. The concept of self-esteem includes the belief that there is a human need to see the self as good, competent, and decent, and that this need has both an evaluative and a cognitive component. The importance of the evaluative component is illustrated by the observation that all people at times distort their cognitions, and the interpretations of these cognitions, in order to raise their self-esteem (Aronson et al. 2007).

Self-Evaluation Maintenance Theory

Self-evaluation maintenance theory (Tesser and Campbell 1982) focuses on emotional arousal and predicts that emotional arousal affects self-evaluation maintenance processes, and that people will downgrade their ratings of others in order to maintain their own sense of self-worth. This theory may have relevance for understanding the private versus public behavior of individuals with narcissistic traits, particularly when that person feels envious of another.

In one study of self-evaluation maintenance theory, participants rated another person’s performance less favorably when the task was important to the rater’s own abilities (Tesser and Campbell 1982). In a related experiment (Morf 1993), students with varying degrees of “narcissism,” as measured by the Narcissistic Personality Inventory, were either slightly or substantially outperformed on a task that was important to their own self-esteem. The more narcissistic individuals anonymously (but not necessarily publicly) rated the other person more negatively than did the less narcissistic individuals, and the more ego-relevant the task, the more the private ratings of the other person were downgraded (Table 27–5).

Table 27–5 Self-Evaluation Maintenance Theory
People will downgrade their ratings of other people in order to maintain their own sense of self-worth. Self-evaluation maintenance theory has implications for understanding the concepts of envy and narcissism.

The Cognitive Approach to the Self: The Multidimensional Social Self

Deaux (1992) has developed a social psychological model of relationships between self and mental health that revolves around self-definition and the impact of challenges to self-definition on mental health functioning. In this model, self-maintenance is at the center of maintaining overall mental health. The social self is multidimensional and includes the characteristics we attribute to ourselves (self-categorization), how we evaluate ourselves, how important we believe we are, to whom we feel attachment and its intensity, how interdependent with others we believe we are, and how much we believe our behavior is governed or determined by the expectations and the behaviors of others. Multidimensional social self-theory has implications for understanding the roles of culture and gender in self-definition, and also draws upon the literature from attribution theory and locus of control theory.

In research studies conducted by Swann and his colleagues, when mildly depressed and nondepressed college students were given bogus ratings of apparent artistic or athletic ability after an interview, and then told they could follow up with a clinician to hear more about their ratings, nondepressed students did not want to hear any more about their supposed limitations. Depressed students did. Both groups were willing to hear more praise about what they perceived to be their strong points. In another study series, it was determined that married people with negative self-views were more inclined to remain in relationships with spouses who thought poorly of them. Finally, people with low self-esteem were more inclined to quit their jobs when told they were receiving pay increases as compared to pay decreases.

Depressed people who hold negative views of the self may seek self-verification of their negative self-views, even when this contributes to lowered self-esteem and increasing depression (Giesler et al. 1996). In a comparison of clinically depressed persons, nondepressed persons with low self-esteem and nondepressed persons with high self-esteem, 82% of the depressed participants chose to receive unfavorable feedback, as compared with 64% of the low self-esteem participants and 25% of the high self-esteem
participants. The depressed persons also tended to ignore opportunities to experience favorable feedback, although they wanted feedback of some kind and were not passive. Clinically depressed children and adolescents expressed more interest in negative feedback than did their non-depressed counterparts, and this association was more related to cognitive rather than to emotional aspects of their self-view (Joiner and Wagner 1995).

Unlike persons with chronically low self-esteem, however, the low self-esteem experienced by the depressed individual may be state dependent, and subject to remission when depression lifts. Clinically, this fluctuation in self-assessment by a patient who is seen on an ongoing basis may perplex both the patient and the treating psychiatrist. Nevertheless, during the depressed state, the patient likely will hold tenaciously to her/his negative self-evaluation, and attempt during those times to confirm that self-view and act on it, sometimes with tragic results.

There is evidence that people with low self-esteem pursue social relationships and social situations that confirm their core self-conceptions, and display cues that communicate how they perceive themselves and want to be perceived by others (identity cues). People also interact in ways that elicit feedback from others that confirm their predominant self-conceptions, and selectively attend to and process interpersonal feedback including negative self-concept. From the standpoint of psychiatry, transference and projective identification could be viewed as a way of interacting to get the psychiatrist to confirm the negative view of the self. Swann and Read (1981) have demonstrated empirically that if people with negative self-views think that their interaction partner views them favorably, they will intensify their efforts to appear unworthy of this positive regard (Table 27–7).

<table>
<thead>
<tr>
<th>Table 27–7</th>
<th>Self-Verification Theory</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Self-verification theory</strong> predicts that people want others to provide continuity in their experience of the self (the self-schema). It has implications for understanding depression and understanding of transference and projective identification because individuals with negative self-views tend to (unwittingly or unconsciously) solicit unfavorable information about themselves from others, possibly to promote the perception of prediction and control by fostering intrapsychic and interpersonal coherence and stability.</td>
<td></td>
</tr>
</tbody>
</table>

Schemas and Their Relationship to Construction of the Self

The situational activation of cognitive schemas is “automatic” and as such is outside the individual’s control and awareness. Cognitive “schemas” are used to look at ambiguous external and internal situations (see the chapter 26, this section). Schemas are based on previously acquired information, and are mental structures that automatically, quickly, and often stereotypically (without one’s awareness) organize knowledge about perceptual experiences. This influences the information we notice and think about (Payne, 2001, Correll, et al. 2002, Janicik and Larrick, 2005). Individuals within different cultures also learn differing cultural causal theories (often attribution models) about what explains our own and others’ behavior and feelings (Nisbett and Wilson 1977, Gavanski and Hoffman 1987, Wilson 2002). Implicit personality theories are types of popular schemas that people use to group various kinds of personality traits together to draw conclusions about the nature of other individuals. These implicit personality theories also differ among cultures, and cultural assumptions are embedded in them.

One popular implicit cultural theory that has been experimentally demonstrated is the American assumption that “what is beautiful is also good” (Dion et al. 1972). As a result of this popular “theory,” beautiful children and adults get more parental attention, more teacher attention in school, and faster promotions at work. This finding has implications for psychiatrists who treat individuals who do not meet cultural standards of beauty, and can provide insight when advising members of the criminal justice system and other social institutions.

People also use “self-schemas” to organize information about themselves (Markus 1977). This information, and the way in which it is organized, contributes to the development and maintenance of the self. Like other schemas, self-schemas are “short-cuts” and exert their effects especially in ambiguous circumstances where some of the information is consistent with the schema and the rest is ambiguous. Self-schemas tend to be self-perpetuating, and so the view of the self is not easily changed (Shadel et al. 2004). The intractability of personality disorders may be related to this phenomenon.

When Facts and Self-Schemas Collide: Cognitive Dissonance as a Theory of the Self

Leon Festinger (1957) was inspired to develop the theory of cognitive dissonance after he observed that members of a UFO doomsday cult increased their proselytization after the leader’s prophecy failed. Cognitive dissonance originally was proposed as a theory of attitude change but now is viewed as a self-theory (Aronson et al. 2007). Cognitive dissonance is a feeling of discomfort caused by performing an action that is discrepant from one’s customary self-conception (conscious view of the self). The theory proposes that dissonance is strongest when a discrepancy has been noticed between a core area of one’s self-concept and one’s overt behavior, because this creates a feeling of “shame.” This leads to either change in attitude, change in behavior, some kind of self-affirmation, (Shakespeare’s “The lady doth protest too much, methinks.”), or some rationalization of the behavior (Table 27–8).

<table>
<thead>
<tr>
<th>Table 27–8</th>
<th>Cognitive Dissonance</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Cognitive dissonance</strong> is a feeling of discomfort caused by performing an action that is discrepant from one’s self-conception, leading to a feeling of shame and lowered self-esteem. The theory has implications for understanding self-affirmations and rationalizations, and may have importance in understanding when patients “flee awareness” through substance abuse, interpersonal confrontations, suicide attempts, or dissociation.</td>
<td></td>
</tr>
</tbody>
</table>

Not included in Festinger’s theory, but sometimes observed clinically, is that when one realizes that current social behavior and the self’s internal standards and values are not in harmony, one may “flee awareness”
Obedience to Authority and Diffusion of Responsibility

It has been argued that the traumatic experiences of the Holocaust gave birth to the field of social psychology. Psychiatrists looked for an explanation in individual pathology, developing the construct of the “authoritarian personality” (Adorno et al. 1950) to describe a set of character traits related to acceptance of authoritarian doctrines.

More chilling to students of the evolving field of social psychology were the observations of Holocaust survivor and political philosopher Hannah Arendt, who argued that many of the principal perpetrators of the Holocaust, such as Adolf Eichman, were not authoritarian, particularly aggressive “monsters” but rather ordinary bureaucrats who did what they were told without questioning orders. Although the acts that were carried out proved to be stressful to some perpetrators, this stress merely prompted them to search for less personal methods of accomplishing their mission, such as delegating part of the duties to subordinates and remaining in one’s office or leaving the environment for a time (Browning 1998). Arendt argued that the Holocaust, for the most part, was carried out by ordinary people caught up in social forces that affected their behavior. Social psychologists set out to understand the nature of these forces.

In an effort to determine experimentally whether ordinarily nonviolent people would ignore obvious injustice and inflict pain on another person in response to social pressure, Stanley Milgram (1975) conducted a now famous series of experiments. He demonstrated that 61–66% of the people who were studied, despite sometimes feeling extreme emotional stress about doing so, were willing to subject “others” to very painful electric shocks (or so they believed) when told to do so by an authority figure. Further, none of the minority of participants who did refuse to administer these shocks insisted that the experiments be terminated, nor checked on the welfare of the “victims.” Milgram developed two main theories to explain his results: “conformism” due to a lack of a reference point about how to behave in an unfamiliar situation, and “agency theory,” which argued that the person who is obedient comes to view himself as an instrument for carrying out another’s wishes, and feels no responsibility for the action (related to attribution theory).

**Bystander effect.** Observers of a victim see other bystanders present, and each bystander feels less responsibility to help because each one believes (1) someone else will help or should help and (2) each bystander feels less personal responsibility because the others are there also (“diffusion of responsibility”).

Summary

In this chapter, we have discussed the ways in which the constructs and findings of social psychology can enrich the field of psychiatry. We introduced the concept of “social cognition.” We demonstrated how attribution theory plays a role in several cognitive vulnerability models of depression, as well as in helping behavior and popular cultural causal assumptions about behavior and personality. We also described how positively skewed reality distortions (positive illusions) contribute to resilience in the face of adversity, and how adversity can contribute to personal growth.

We explained the social psychological perspective on self-report depression scales, and how patient “recall” of past emotional states and symptom changes may actually represent reconstructions based on implicit personal theories of change and other cognitive distortions. The situational activation of cognitive schemas, and their relationship to the experience of the self, are fruitful areas for future investigation at the interface of psychiatry and social psychology.

We compared some of the social psychological theories of the experience of the self with those commonly alluded to in the psychiatric literature: specifically, how the theories of Freud, Klein, Kernberg, and Kohut contrast with self-theories within social psychology such as self-evaluation maintenance theory, the multidimensional social self, and
self-verification theory. We also used social psychological models of self-maintenance to explain the apparently paradoxical behavior of individuals with low self-esteem, and depressed patients, as they seek negative feedback. Finally, we explained the relevance to psychiatric practice of cognitive dissonance theory and the concepts of obedience to authority, diffusion of responsibility, and the bystander effect.

References

Psychoanalysis is a clinical therapy originally developed by Sigmund Freud (1856–1939) for the treatment of the neuroses. The term also refers to a theory of psychopathology underlying the therapeutic practice; a general theory of the mind, based on the understanding arising from the clinical procedure and other sources; and a mode of research into mental life that is inherent in and inextricably intertwined with the therapeutic process. Although the contemporary practice of psychoanalysis derives historically from Freud’s original contributions, it has evolved like any other discipline. Freud’s written work can no longer be regarded as constituting a definitive contemporary account of psychoanalysis. Indeed, it would be difficult for current psychoanalysts to agree definitively on what constitutes psychoanalysis. What these chapters hope to impart is how psychoanalytic theory has evolved, often in disparate directions, and how modern psychoanalytic theories inform our understanding of our often complex mental processes, motivations, and behaviors. For both ease of reference and the sake of historical continuity, this section is in part organized around the contributions of those individual thinkers who have had a major impact on the development of psychoanalysis. Beginning with Freud and the inception of psychoanalysis, the section traces the important trends in the maturation of analytic theory and its current state of development.

**Development and Major Concepts**

**Freud’s Contributions**

**Dreams**

Freud’s study (1900, 1901) of dreams during his self-analysis and in his work with patients resulted in an elaborate understanding of the workings of the mind. The analysis of dreams continues to hold a prominent position in psychoanalytic practice. Dreams provide a wealth of information about the influence of unconscious wishes, fantasies, and defense mechanisms in the shaping of conscious mental content. Without the benefit of contemporary electrophysiological data, Freud believed that dreams functioned to preserve sleep and to prevent awakening, in the presence of nocturnal stimuli, both exogenous (e.g., noise, tactile stimulation) and endogenous (ongoing mental conflict) that must be managed to preserve sleep. Dreams give expression to unconscious wishes in disguised form and generally represent their fulfillment or gratification. Analysis of dreams can provide
conscious access to unconscious drives, wishes, fantasies, and associated repressed infantile memories, providing what Freud called the “royal road to the unconscious.”

The dream that is remembered on awakening is referred to as the manifest dream. It is the product of mental activity that has woven together a number of conscious and unconscious elements into a hallucinated experience that is recalled like a story or a play. Its component elements include sensory stimuli occurring during sleep, the day residue, and the latent dream content. The day residue consists of experiences of events of the preceding day or days, often associated in the mind with unconscious wishes. The latent dream content is the set of unconscious infantile urges, wishes, and fantasies that seek gratification during the dreaming state of blocked motor discharge and regression.

Freud hypothesized a dream censor whose function is to keep the unconscious latent content from conscious awareness, thereby preventing the emergence of anxiety and awakening from sleep. The surreal and fantastic quality of the remembered manifest dream is a reflection of the influence of primary process unconscious mentation (Table 28–1) (depiction of immediate gratifications, absence of the rules of logic of conscious thought, merging of past and present, absence of negatives, loss of distinction between opposites, and representation of a whole by a part) and of the activity of the dream work, a set of mental mechanisms designed to disguise and distort the latent content in keeping with the function of the dream censor.

The specific mechanisms of the dream work include condensation, displacement, symbolization, and projection. Condensation is a process by which several unconscious elements are represented by a single image or event in the dream. In displacement, the psychic intensity or emotional charge belonging to a latent element is attached to a more neutral or innocuous dream image, creating a shift of emotional emphasis and directing attention away from an unconsciously charged element. Symbolization is a mechanism by which an unconscious idea is represented in the dream by something else, usually associatively connected (e.g., a gun symbolizing a penis). Freud emphasized that there are few symbols common to everyone; symbols that are chosen by an individual are most often unique to that individual. The mechanism of projection results in the depiction of unconscious wishes or motives originating in other figures in the dream, placing them outside oneself. Finally, the various images and themes of the dream are organized by the process of secondary elaboration into the relatively coherent story line of the manifest dream (Figure 28–1).

In psychoanalytic treatment, the analysis of dreams attempts to take this process backward, starting with the patient’s narration of the dream and then observing the patient’s associations to the manifest elements, with the goal of obtaining insight into the dreamer’s unconscious wishes, memories and infantile fantasies, and processes of defense. Even with our understanding of the origin of neurophysiological dream activity, the process of dream analysis continues to provide a rich source of data about the associative connections between mental representations, memories, unconscious wishes and fantasies, and the construction of thought (Winson 1985, Reiser 1990).

### Childhood Sexuality

In his analyses of adult patients and observations of children, Freud (1905a) became convinced of the influence of early sexual fantasies on the formation of neurotic symptoms and of the universality of sexual wishes throughout life, including early childhood. The term sexuality is used in this context to refer not exclusively to adult genital sexuality but to a variety of body stimulations that are pleasurable and sensually gratifying. He postulated a developmental sequence of body zones that become primary foci of erotic sensations and mental organization (Table 28–2): oral, anal (including perianal and urethral), and genital (phallic). During development, there is a more or less orderly progression from one zone to the next, with pleasure being derived from sucking, biting, tasting, touching, looking, smelling, filling, emptying, penetrating, and being penetrated. The urge to do each of these, in relation to each specific erogenous zone, is referred to as a component instinct. In adult sexuality, the component instincts come together in foreplay, which is used in this context to refer not exclusively to adult genital sexuality but to a variety of body stimulations that are pleasurable and sensually gratifying.
The first of the phases described by Freud is the oral phase (Table 28–4), which encompasses approximately the first 18 months of life. During this phase, the mouth, lips, and tongue are the primary sources of sensual gratification. The activities of sucking, swallowing, mouthing, and biting as well as the experience of being held during feeding form a cognitive template for the organization of fantasy and relatedness to others. The infant at this stage is dependent on mother for nurturance, protection, and sustenance. A favorable outcome of this stage is the development of a capacity to feel trust and safety in a dependent relationship, a readiness that needs will be recognized and gratified, and a minimum of conflict about aggressive wishes occurring during moments of frustration. Excessive neglect or deprivation during this period may result in adult feelings of insufficiency of issues pertinent to that phase. Fixations result in continued manifestations of phase-specific issues in a person’s behavior, influencing later personality adjustment (e.g., the anal organization of the obsessional character). Regression (Table 28–3), a return to a less mature level of mental organization, may occur in the context of stressors or conflict that overtax the adaptive capacities of an individual. Regression, which often serves defensive or self-protective purposes, will be determined both in kind and in degree, by fixations in psychosexual development.

The first of the phases described by Freud is the oral phase (Table 28–4), which encompasses approximately the first 18 months of life. During this phase, the mouth, lips, and tongue are the primary sources of sensual gratification. The activities of sucking, swallowing, mouthing, and biting as well as the experience of being held during feeding form a cognitive template for the organization of fantasy and relatedness to others. The infant at this stage is dependent on mother for nurturance, protection, and sustenance. A favorable outcome of this stage is the establishment of a capacity to feel trust and safety in a dependent relationship, a readiness that needs will be recognized and gratified, and a minimum of conflict about aggressive wishes occurring during moments of frustration. Excessive neglect or deprivation during this period may result in adult feelings of insufficiency of issues pertinent to that phase. Fixations result in continued manifestations of phase-specific issues in a person’s behavior, influencing later personality adjustment (e.g., the anal organization of the obsessional character). Regression (Table 28–3), a return to a less mature level of mental organization, may occur in the context of stressors or conflict that overtax the adaptive capacities of an individual. Regression, which often serves defensive or self-protective purposes, will be determined both in kind and in degree, by fixations in psychosexual development.

The oral phase (see Table 28–4) emerges with the development of increasing neuromuscular control of the anal and urethral sphincters and takes place from about 18 months to 3 years. Sensual pleasure becomes most highly localized in the anal and rectal mucosa. Fantasy organizes around anal pleasure and anal functions, such as withholding, expelling, and controlling. Because of the child’s increased motor skills, language development, and emerging autonomy, she or he is expected to take more of an active part in self-care activities, including using the toilet. Related to toileting, power struggles may ensue around the child’s soiling or withholding. Anger is felt toward those in control of this educative process, but the child also wishes to please them. The child in the anal phase experiences considerable ambivalence around expelling versus retaining (giving versus keeping), obedience and submission versus defiance and protest, and cleanliness and orderliness versus messiness. The working through of these areas of intense ambivalence can be complicated if the parents are overly controlling, critical, punitive, or rigidly intolerant of the child’s expressions of aggression and willfulness. Fixation at this stage results in a personality organized around anal erotism and its associated conflicts, characterized by wishes to dominate and control people or life situations, rigidity, defiance and anger toward authority, neatness, orderliness, messiness, parsimony, frugality, and obstinacy (Freud 1908, Abraham 1921, Salzman 1980, Shengold 1988).

The phallic or phallic-oedipal or genital phase (see Table 28–4) occurs from the ages of 3 to about 5 or 6 years. At the onset of this period, sensual pleasure has become most highly focused around the genitals, and masturbatory sensations more closely resemble the usual sense of the word sexual. The child at this time has become even
more autonomous and has more sophisticated motor and language skills, conceptual capabilities, and elaborate fantasies. The child is better able to recognize feelings of love, hate, jealousy, and fear; has a more distinct recognition of the anatomical difference between the sexes; and appreciates that the parents have an intimate sexual relationship from which the child is excluded. Thinking about relatedness to others shifts from the largely dyadic (mother–child) quality of the prephallic phases to an appreciation of relational triangles.

Freud recognized in his patients’ associations that there were regularly occurring incestuous fantasies and wishes toward the parent of the opposite sex that were involved in the formation of neurotic difficulties. He termed this phenomenon the Oedipus complex, in reference to the story of Oedipus, who unknowingly killed his father and married his mother. In the midst of the Oedipus complex, the child wishes to possess exclusively the parent of the opposite sex and to eliminate the parent of the same sex. The jealousy and murderous rage felt toward the same-sex parent are accompanied by fears of retaliation and physical harm. Because these fantasies are associatively linked to pleasurable genital sensations, the child has specific unconscious fears of being castrated, which Freud referred to as the castration complex.

The oedipal phase proceeds differently in boys and girls. The little boy has maintained his primary attachment to his mother, but he now wants to sleep with her, see her naked, touch her, and marry her. He feels jealousy and hostility toward his father, seen as his rival. His fears of retaliatory castration, while wanting to maintain his loving relationship with father, lead him to renounce his wishes and to strengthen his identification with his father. He seeks to become more like father and to find someone else like mother.

Freud’s ideas about the girl’s Oedipus complex have stirred much criticism and controversy. Freud (1924b, 1925) believed that the little girl comes to recognize her lack of a penis with feelings of loss, narcissistic injury, anger at mother, and envy of men. She turns toward father to provide her with a penis substitute in the form of a baby. She fantasizes a rivalry with mother and fears punishment, loss of love, and genital damage. Eventually she returns to her identification with mother. Whereas the castration complex leads to the resolution of the Oedipus complex in boys, the castration complex precedes and creates the Oedipus complex in girls. A number of contemporary theorists have disputed Freud’s views of feminine development, citing observational evidence of girls’ primary feminine identification, positive experience of their female genitals, and wishes to have a baby before the oedipal situation (Blum 1976, Klee- man 1976, Stoller 1976, Gilligan 1982, Chehrazi 1986). Envy of men may be seen, in a sociohistorical context, as a by-product of cultural devaluation of women (in an egalitarian society, a predominating sense of penis envy may indicate neurotic or narcissistic difficulties). Boys too are susceptible to fantasies of genital inferiority on comparing their small penises to larger adult genitals (Horney 1932).

Successful passage through the phallic phase includes resolution of the Oedipus complex and repression of oedipal fantasies. The child internalizes the parental prohibitions and moral values and demonstrates a greater capacity to channel instinctual energies into constructive activities. Excessive conflict or traumatization during this phase may lead to a personally organized around oedipal fantasies and conflicts or a pru veness to defensively regress to anal or oral organization.

During the latency phase (see Table 28–4), from age 6 years to puberty, play and learning take a prominent position in the child’s behavioral repertory as cognitive process mature further. Although Freud believed that the sexual urges become relatively quiescent during this phase, observation indicates that they are expressed in derivative form in the child’s play (Sarnoff 1976). At puberty, and through adolescence, genital urges once again predominate, but there is now a consolidation of sexual identity and a movement toward adult sexuality (Figure 28–2).

Libido Theory

Freud’s continued consideration of the sources and nature of the sexual drives led to his dynamic model of the mind referred to as libido theory (Table 28–5). This theory attempted to explain the observation that behavior and mental activity are not only triggered by external stimuli (as in the reflex arc) but also generated by primary internal processes. As a biologist, Freud hoped to understand the somatic origins of mental activity and used the concept of instinct (Treib, “drive”) to do so. The psychoanalytic use of the term instinct differs from that of biology, which refers to innate, inherited, unlearned, stereotypical, species-specific behaviors. Freud (1915) defined instinct as “a concept on the frontier between the mental and the somatic, as the psychical representative of the stimuli originating within the organism and reaching the mind, as a measure of the demand made upon the mind for work in consequences of its connection with the body.” Regardless of the specifics of their physiological origins, derivatives of the instincts are experienced mentally as compelling urges and a source of motivation.

Although Freud had given up the idea that sexual traumatization was always the cause of psychoneurotic symptoms, he maintained the view that the sexual instinct played an etiological role in the neuroses and that sexual stimulation exerted a predominant force on mental activity throughout life. Freud termed this force libido. The discharge of libido is experienced as pleasure; the welling up of libido without discharge is felt as tension or displeasure. According to the pleasure principle, the individual seeks pleasure (through the discharge of libidinal tension) and avoids displeasure. The primary process quality of unconscious mentation follows the pleasure principle as it maintains its focus on the gratification of wishes. As the mind develops, conscious mentation becomes more governed by the reality principle (Freud 1911a), involving a shift from fantasy to perception of and action on reality. The secondary process form of conscious thought follows the reality principle. Under the influence of the reality principle, gratification of wishes may be delayed with the aim of eventually achieving greater and/or safer pleasure.

The sexual instinct has four defining components: source, pressure (or impetus), aim, and object (Freud 1905a, 1915). Source refers to the biological substrate of the instinct. Pressure is the amount of force or “demand for work” of the instinct. The aim is the action designed to accomplish release of tension and satisfaction. An object is the target

Section IV • Psychological and Social Science Foundations

because it was based on 19th century German scientism, it has served as a useful metaphor to understand pleasure, attachments, and the dynamic processes of mental activity.

From the Topographical to the Structural Model

As psychoanalytic theory developed during the 20 years after Freud’s writing (1900) of *The Interpretation of Dreams*, it was built on the foundation of the topographical theory of desire, the person or thing through which gratification is accomplished. Freud (1914a, 1915) went on to theorize that libido can be invested in or attached to representations of others in the mind or to the mental structures themselves, a phenomenon referred to as *cathexis*. Libido invested in mental representations of others is termed *object libido*; cathexis of the libido to the ego or self-representation is referred to as *ego-libido*. Although the libido theory has been criticized

(Time 28–6). This theory was able to explain the observations that patients under hypnosis, or using free association, were able to become consciously aware of memories or motives for which they had no prior conscious awareness, the causal role of these elements in symptom formation and other psychological events, and the apparent opposition the mind exerted against the awareness or recall of these unconscious elements.

</table>

According to the topographical theory, three regions or systems of the mind exist as defined by their relationship to conscious thought: the conscious, preconscious, and unconscious. The conscious mind registers sensations from the outside world and from internal processes and is the agency of ordinary wakeful thought. Conscious mentation follows the reality principle and uses secondary process logic. The preconscious includes mental contents that can gain access into consciousness by the focusing of attention. The unconscious is defined from three basic angles: descriptively, it consists of all mental processes and contents operating outside conscious awareness; dynamically, these processes and contents are kept actively repressed or censored by the expenditure of mental energy to prevent the anxiety or repugnance that would accompany their conscious recognition; and as a mental system, it is a part of the mind that operates in accordance with the pleasure principle using primary process logic.

Over time, Freud encountered clinical phenomena that were not adequately accounted for by the topographical model. Resistance to free association did not appear to be governed by conscious processes, but rather was operating unconsciously. In addition, the topographical model did not help explain self-defeating behavior and the unconscious need for punishment. In time, Freud revised his theory of mental systems to include the structural model, but the useful conception of the dynamic unconscious and the particular qualities of conscious, preconscious, and unconscious mentation have been retained.

Theory of Narcissism

Freud (1914a) was led to his theory of narcissism by his consideration of a number of psychological phenomena including psychosis, hypochondria, different types of loving or erotic attachments, and the relationship of self-love or self-regard to the judgmental processes of the conscience. The term narcissism was derived from the myth of Narcissus, who fell in love with his own reflection, and hence, refers broadly to self-love. Freud noted that although a narcissistic attitude had been described as a component of certain psychiatric disorders, narcissism was seen more extensively and could be considered a part of normal development. Using the terminology of libido theory, Freud observed that psychotic individuals, with their turning inward and away from the external world and with their megalomaniacal preoccupations, appeared to have withdrawn libido from objects and attached it to the ego (self); however, phenomena similar to megalomania, such as magical thinking and overestimation of wishes and thoughts, could be seen early in normal development. During earliest infancy, libido is originally attached to ego, a state called primary narcissism. Libido then becomes attached progressively to love objects in the form of object libido. This can be withdrawn back to the ego, referred to as secondary narcissism.

In all mental functioning, it is possible to observe the balance between libido deployed toward objects and libido withdrawn into the ego. For example, when a person is in love, much libido is attached to the loved object, even to the extent that the person feels himself or herself diminished (from decreased ego libido). During physical illness or hypochondriacal states, libido is pulled toward the ego so the person appears preoccupied with the body and uninterested in the world. According to the pleasure principle, the mind seeks to discharge libido, and if it is dammed up, symptoms will result. In neurotic persons, excess object libido has accumulated and, undischarged, produces anxiety. In psychotic persons, ego libido has been prevented from being discharged outward, so it is discharged inward, resulting in hypochondriac anxiety and megalomania.

Narcissistic phenomena are involved in certain love and erotic relationships. In infancy, the primary attachment to mother has a self-preservative quality involving ego libido and is referred to as an anaclitic attachment. Some adults continue to seek out anaclitic love attachments, wishing to be fed and protected. Other individuals may form narcissistic attachments, looking for someone who resembles oneself, the way one was, or the way one would like to be. Often the love of parents for their children may involve a revival of their own narcissism, reflected in the overevaluation or overindulgence of a child.

Internal judgmental processes and self-regard are also addressed by the theory of narcissism. In normal adults, most evidence of the operation of ego libido has been repressed. A new target of self-love has been constructed, the ego ideal, a forerunner of the superego concept, consisting of ideas and wishes for how one would like to be.
Similarly, love objects may become the subject of idealization. Freud theorized a separate psychic agency that attends to ensuring narcissistic satisfaction and measuring the self-reflection, censoring, and repression. Living up to the ideal, loving oneself, and being loved reflect attempts to restore a state comparable to the primary narcissism of infancy.

Melancholia
In *Mourning and Melancholia*, Freud (1917) developed a theory to explain processes of guilt, internal self-punishment, and depression. To do this, he contrasted states of grief or mourning with the condition of melancholia. Both have in common the experience of pain and sadness, and both are brought on by the experience of loss, but the person in mourning maintains her or his positive self-regard, whereas the person with melancholia feels dejected, loses interest in the world, shows a diminished capacity to love, inhibits all activities, and exhibits low self-regard in the form of self-reproaches. In mourning, libido is gradually withdrawn from the object attachment; in melancholia, the ego feels depleted or comes under attack as though “one part of the ego sets itself over against the other, judges it critically, and as it were, takes it as its object.” This critical agency (again a theoretical forerunner of the superego) comes to operate independently of the ego.

The self-accusations of the person with melancholia seem to fit best with criticism that might be leveled against the lost object. In the case of suicidal impulses, the melancholic person seems to be directing at himself or herself the sadism and murderous wishes felt toward the disappointing or lost other. Freud theorized that in the context of the loss of an ambivalently held object, the ego incorporates, or forms a narcissistic identification with, the object. Hostility originally felt toward the object is now directed at the self, giving rise to feelings of torment, suffering, and self-debasement. A predisposition to melancholia may thus result from forming narcissistic object attachments and identifications.

**Dual-Instinct Theory**
Over time, Freud’s theory of aggression evolved. He had originally considered two types of instincts, the sexual and the ego (self-preservative) instincts, and considered sadism to represent a fusion of the two, with hostility occurring in the context of frustrated libidinal strivings. However, this theory did not adequately address psychological situations in which destructive tendencies seem to be operating independently of libidinal or self-preservative drives. In addition, certain types of pathological conditions seemed to defy the pleasure principle in that experiences of unpleasure were continuously repeated, a phenomenon referred to as the *repetition compulsion* (Freud 1920, 1923, 1924a). Patients with traumatic neuroses were observed to think and dream repeatedly of the painful experiences that brought about their disorder. Other patients with masochistic qualities unconsciously set up life situations in which they suffer. Some individuals in psychoanalytic treatment manifest negative therapeutic reactions, in which insights that ought to lead to symptomatic improvement produce worsening instead.

Freud concluded that there must be a separate instinct of aggression, whose aim is destructiveness. The aggressive drive is at work in impulses to harm, in the desire for control and power, in sadistic or masochistic behaviors, in guilt and depression, and in the persecutory fears of paranoid individuals. Freud theorized two general forces at work in the human psyche: the *life instinct* (Eros or libido), operative in positive, synthetic constructive activities; and the *death instinct* (Thanatos), which propels the human organism toward destruction, disarray, and eventually entropy. Although the concept of a death instinct has been rejected by most psychoanalysts, the concept of an aggressive drive and its related conflicts has been of considerable clinical utility.

**Structural Model**
On the basis of the preceding considerations, Freud (1926, 1933) revised his theory of the mind into what is now known as the structural or tripartite model (Table 28–7). He conceived of three mental agencies operating in the psyche: the id, the ego, and the superego. The id is the biological source of instinc turbulent drives, operating unconsciously and following the pleasure principle. The activity of the id generates the motivational push for gratification of sexual and aggressive wishes.

The ego grows out of the id early in human development: it was initially defined by Freud as the “organized portion of the id.” Its functions include perception, interpretation of perceptions, voluntary movement, modulation of affects and impulses, cognition, memory, judgment, and adaptation to reality. Subject to conflicting forces from the id, the superego, and reality, the ego synthesizes mental compromises that provide gratification of instinctual wishes in accord with reality considerations and the moral demands of the superego.

The superego, which develops as a growth of both the ego and id, consists of the moral standards, values, and
prohibitions that have been internalized throughout childhood and adolescence. It is the source of internal punishment, which is felt as guilt, and of internal reward. Early in development, the superego has a harsh and archaic quality. During maturation under optimal conditions, it becomes less harsh and comes to include loving components as well. In the structural model, the ego ideal (discussed earlier) is considered a component of the superego, accounting for feelings of shame and pride.

**Anxiety and Symptom Formation**

With the elaboration of the structural theory, Freud progressively viewed the nature of anxiety and the origin of symptoms (Figure 28–3) differently. According to his original theory, anxiety resulted from the accumulation of undischarged sexual tensions, caused by inadequate sexual activity in the actual neuroses or by inhibitions due to repression in the psychoneuroses. Later, it became clear that anxiety was more closely related to fear, occurring in response to perceived dangers, either external or internal. This led to a focus on the ego, one of whose functions is to anticipate and negotiate danger situations (Freud 1926). A dangerous or traumatic situation is one in which excessive stimulation threatens to overwhelm the ego’s capacity for delay and compromise.

The original traumatic situation is birth, at which time the immature psychic apparatus of the newborn cannot manage the upsurge of instincual tensions accompanying extrauterine life. During subsequent development, other characteristic danger situations arise (Table 28–8). Because of the helplessness and vulnerability of the infant, the major danger during the oral phase is loss of the primary object, typically mother. Later, as the child has greater autonomy and a sense of the separateness of parental objects, loss of the object’s love comes to be the leading danger. During the phallic phase, the principal danger is the threat of castration or body injury. As the superego develops, the primary danger becomes guilt, the internalized punishment or loss of love of the superego.

**Table 28–8 Typical Situations of Danger**

| Fear of instincts (traumatic overstimulation) |
| Fear of object loss                             |
| Fear of loss of love                            |
| Fear of castration (body injury)                |
| Fear of guilt (moral anxiety)                   |

In this model, then, the ego is able to anticipate the potentially traumatic danger situations associated with unconscious wishes or impulses that are pushing toward conscious awareness. It mobilizes a small amount of alerting anxiety, referred to as signal anxiety, which in turn activates repression and many other defensive operations to prevent the wish or impulse from emerging into conscious awareness.

The ego has as one of its tasks the continual formation of compromises among id wishes, the prohibitions, and moral standards of the superego, and the dictates of reality. If these compromises are successful, anxiety will operate predominantly on a signal level and behavior will be both sufficiently gratifying and acceptable in reality. A symptom neurosis occurs if these compromises are felt as uncomfortable, painful, or maladaptive. For example, in the development of a phobia, a conflictual unconscious wish and its associated fantasies have been successfully displaced outward, or externalized, and attached to something in the environment that can be avoided. Although the compromise works, in that it prevents conscious recognition of the wish and its associated unconscious fears, the resulting phobic avoidance may lead to a restriction of adaptive functioning. In the neuroses, there is recognition of the difficulties created by symptoms and acknowledgment of a desire to change. In the character neuroses, on the other hand, problem behaviors and modes of experiencing, which result from rigid and repetitive use of particular defense constellations, are felt as relatively comfortable and ego-syntonic. Because character-disordered individuals often resist the notion that their life difficulties are the result of their own internal processes, a first order of business in their psychoanalytic treatment is to transform their defenses and compromises into ego-dystonic experiences in order to create the motivation to change.

**Post-Freudian Ego Psychology**

**Ego, Defense, and Adaptation**

With the publication of *The Ego and the Mechanisms of Defense*, Anna Freud (1936) categorized and developed the first comprehensive theory of mechanisms of defense (Table 28–9). In discussing the preliminary stages of defense that are first used by the ego to avoid pain from the external world, she succeeded in integrating two main themes in the development of the ego concept: defense and relations with external reality. Anna Freud advocated a shift of the analyst’s attention to the ego as “the proper field” for observation, in order to get a picture of its functioning in relation to the other two psychic structures, id and superego. In contrast to impulses of the id that push toward consciousness, the unconscious aspects of the ego do not push toward conscious awareness and therefore offer a greater challenge to the analyst. "All the defensive measures of the ego against the id are carried out silently and invisibly" (Hartmann 1939, p. 8) and must be inferred from their influence on the patient’s associations. This requires a shift in the analyst’s method of observation. This more detailed methodical attention to the mind’s surface, which includes manifestations of unconscious ego activities, provides a much clearer view of the actual workings of the mental apparatus.

In describing three types of transference (transference of the libidinal impulses, transference of defense, and acting...
Ten Mechanisms of Defense (Anna Freud)

<table>
<thead>
<tr>
<th>Mechanism</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Repression</td>
<td>This process consists of the expelling and withholding from conscious awareness an idea or feeling. It may operate by excluding from awareness what was once experienced on a conscious level, or it may curb ideas and feelings before they have reached consciousness.</td>
</tr>
<tr>
<td>Regression</td>
<td>This means a return to a previous stage of development or functioning to avoid the anxieties or hostilities involved in later stages; a return to earlier points of fixation embodying modes of behavior previously given up.</td>
</tr>
<tr>
<td>Reaction formation</td>
<td>This is a method for the management of unacceptable impulses by permitting expression of the impulse in an antithetical acceptable form.</td>
</tr>
<tr>
<td>Isolation</td>
<td>This process is characterized by the intrapsychic splitting or separation of affect from content, resulting in repression of either idea or affect or the displacement of affect to a different or substitute content.</td>
</tr>
<tr>
<td>Undoing</td>
<td>A forbidden offensive act is ritualistically and magically nullified by abreaction, often by religious or self-punitive expiation.</td>
</tr>
<tr>
<td>Projection</td>
<td>Unacceptable impulses or ideas are attributed to someone or something else.</td>
</tr>
<tr>
<td>Turning against the self</td>
<td>Aggressive impulses originally directed toward someone else (the object) are directed back to the self.</td>
</tr>
<tr>
<td>Reversal</td>
<td>This is turning into the opposite and often applies to affects.</td>
</tr>
<tr>
<td>Sublimation (displacement)</td>
<td>The gratification of an impulse whose goal is retained, but whose aim or object is changed from a socially objectionable one to a socially valued one.</td>

Table 28–9

out), Anna Freud emphasized the importance of interpreting defense first to effect the dynamic struggle at the exact point where it is occurring. The conflict between emergent wishes and the defenses against them is a repetition in the here-and-now of earlier infantile struggles, and learning how and why the patient’s defenses take the particular form they do also valuable information about the development of the ego. Her recommendation that the analyst listen from a point equidistant from id, ego, and superego emphasized the importance of observing neutrally the influence of all three psychic agencies. She advocated that priority be given to the interpretation of the defenses against affects as well as defenses against instinctual drives. Anna Freud’s emphasis on the adaptive nature and purpose of defense was further elucidated by Hartmann (1939), who sought to establish a separate biological substrate for the ego in the concept of adaptation. The ego was to maintain a dynamic equilibrium among the instinctual pressures, internal ideals and prohibitions, and the external environment. Its aims were safety and optimal adaptation to inner and outer demands. The ego’s coordinating function was further elaborated by Nunberg (1931), who referred to the ego’s synthetic function. Waelder (1930) described, in similar terms, the importance of viewing all ego functions from the perspective of an ego-ordinated interaction of trends within the mind representing all the psychic agencies in their instinctual and inhibitory modes. He referred to this as the principle of multiple function. Hartmann further emphasized that it is a mistake to assume that a current function or meaning can be equated with or reduced to its historical precursors and referred to this common type of error as the genetic fallacy.

Modern Structural Theory

Modern structural theory embraces the presupposition underlying Freud’s structural hypothesis that psychoanalysis is primarily a psychology of conflict. That is to say, psychoanalysis approaches mental life from the standpoint of intrapsychic forces in conflict and the compromises that are the outcomes of such intrapsychic conflict. The progressive loosening of modern structural theory from Freud’s reified formulations of id, ego, and superego has resulted in a more clinically based focus on the components of psychic conflict (drive derivatives, anxiety, depressive affect, defenses, reality, and moral considerations) accompanied by an enlargement of the experiential and dynamic realm of conflict. Modern structural theory can be seen as a kind of system theory because it stresses the interrelatedness of all psychic structures and associated behaviors.

These several trends—the jettisoning of Freud’s energy concepts, the expansion of the components of conflict, and adoption of an experience-near clinical language to describe conflict—come together in the work of Charles Brenner, whose contributions of the past four decades chronicle the successive steps in the emergence of modern structural theory as a wide-ranging psychology of conflict and compromise formation. Brenner (1982) proposed a substantive revision of Freud’s structural theory (Brenner 1971a, 1971b, 1979), not only arguing against the extraanalytical (i.e., biological) presuppositions that Freud imported to the structural model, but also calling into question the theoretical soundness of Freud’s definitions of the three psychic structures.

These revisions, taken together, constitute a new language for structural theory. As early as 1971, Brenner argued against the broad, biological meaning Freud imputed to the drives. He defended Freud’s theory of the aggressive drive, which derived from “the accumulation of psychoanalytic evidence,” but not his theory of a biological death instinct. He went on to redefine the drives as “generalizations” about two classes of “wishes” corresponding to two types of motivation. The language of drives was, thus, replaced by a language of wishes—wishes as uniquely individual drive derivatives. Brenner did not see the id. Freud’s repository for the drives, as being as constitutionally determined from the beginning of life and as relatively independent of experience as Freud did. He stressed that from birth, drive-related activities, whether libidinal or aggressive, are influenced by experiential factors that gain expression in ego development.
Because clinical analysis could not support the idea that ego development is separate from drive expression and drive gratification, it followed for Brenner that a sharp distinction between ego and id, even a sharp “heuristic” distinction, could not be maintained. Furthermore, what psychoanalytic theory included under the notion of ego functions is distinguishable from drive, and drive derivatives, only in situations of conflict. Ego functions are the executants of drives and therefore come into opposition to drives only when drive derivatives evoke unpleasant and defense. Conflict is the sine qua non of structural theory.

In stressing the role of the ego in drive gratification from the beginning of life, Brenner was implicitly parting company with Freud, who was content to locate repressed wishes first in the unconscious in the topographical model, and ultimately in the “id of the structural model.” Brenner (1982) also radically redefined the concept of the superego, construing it to be a compromise formation functionally analogous to other compromise formations revealed by psychoanalytic investigation: neurotic symptoms, dreams, delusions, character traits, and so forth. He continued to stress that the superego, as a compromise formation, entered into psychic conflict along with id and ego.

Other Psychoanalytic Perspectives

Object Relations Theory
There is no unitary theory of object relations; rather, it is a variety of theories that differ from each other in important ways and are often contradictory. For some theorists, the concept of “object relations” refers primarily to interpersonal relations; others emphasize that the concept refers not to external interpersonal relationships but to specific intrapsychic structures. In this latter sense, object relations theory can be defined as “a system of psychological explanation based on the premise that the mind comprises elements taken in from outside, primarily aspects of the functioning of other persons. This occurs by means of the processes of internalization. This model of the mind explains mental functions in terms of relations between the various elements internalized” (Moore and Fine 1990). The concept of an inner world inhabited by mental representations of the self and of objects is central to all object relations theories. This inner world is constructed by the individual through the more or less successful integration of the internalized representations of real significant external figures with whom the subject has interacted. In Schafer’s terms (1968, p. 9), “Internalization refers to all those processes by which the subject transforms real or imagined regulatory interactions with his environment, and real or imagined characteristics of his environment, into inner regulations and characteristics.” It is the internalized mental representations of self and objects that influence external interpersonal relations.

Most object relations theorists have worked with patients who suffered from severe, frequently psychotic, psychopathological conditions. Finding previous theories insufficient to conceptualize or treat these disorders, they have searched for new ways to understand their patients. Although all acknowledge their debt to Freud as the originator of the psychoanalytic theory of the mind, object relations theorists were dissatisfied with Freud’s psychoanalytic libido theory, which stressed that the motivation in human beings to relate to others results from internal drives for need gratification.

The term object occurred in Freud’s writings as early as 1905, and he defined the object of an instinct in 1915 as “the thing in regard to which or through which the instinct is able to achieve its aim.” According to libido theory, the object is the creation of the drives. Where there is no inner tension, the pleasure principle reigns, and there is simply a state of quiescence (as with the satiated infant falling asleep at the breast). The prototype for the earliest object relationship is the sucking infant, in whom hunger causes buildup of tension, which is discharged during nursing. The breast is the original object. It gradually becomes associated with need satisfaction in the first few weeks of life. Freud’s choice of the term object, which he used to describe the significant other in human relationships, demonstrates the influence of the mechanistic approach that was guiding his conceptualization. (Freud’s libido theory is more fully discussed in an earlier section of this chapter.)

Libido theory was criticized for its disregard of the person as a social animal, in conjunction with a growing recognition that the existence and quality of our relationships with others determine our adaptations from infancy onward. Freud’s struggle to incorporate object relations can be traced in a series of papers (Freud 1914a, 1915, 1917) culminating in Beyond the Pleasure Principle (Freud 1920).

Melanie Klein

Klein’s theoretical formulations grew out of her observations of the psychotic children she treated. Although some of her controversial ideas have never gained acceptance in mainstream American psychoanalytic thought, her formulations about the importance of aggression and envy, particularly in more primitively organized patients, as well as her understanding of primitive defensive operations, have been central in the thinking of later object relations theorists.

Klein believed that fantasy exists from the beginning of life and is by definition the mental expression of the instincts. She conceptualized the neonate as having an active inner world of fantasy based on its innate libidinal and aggressive drives and their aims. The death instinct is central to Klein’s theories. It finds its expression in earliest infancy in aggression against the object and the self.

Klein modified Freud’s theories of psychological development drastically. As mentioned, she focused predominantly on infancy, describing two psychological “positions” during the first year of life (which was for Freud the oral stage of development). These are the paranoid–schizoid position (Table 28–10) during the first 6 months of life and the depressive position during the second 6 months. The
paranoid–schizoid position is characterized by the defenses of projection, introjection, projective identification, splitting, idealization, omnipotence, and denial (Klein 1946).

These defenses are termed primitive defenses because they have their origin in early development, in contrast to the higher level defenses that evolve later. Projection is the defensive externalization of a threatening internal impulse, ideal, or feeling. Because this is the predominant defense of earliest infancy, the young infant believes that the dangerous impulse, idea, or feeling, which actually originated from within as a manifestation of its own intense drives, is coming from an external source. Therefore, the feared threat is perceived as external rather than internal. This results in anxiety about being attacked from without, termed paranoid anxiety. Introjection takes place when an external object is taken inside (in fantasy) and becomes part of the internal rather than the external world. The paranoid position is characterized by projection and introjection taking place in cycles. Projective identification, as conceptualized by Klein, is a complicated primitive defense that involves the projection of an internal object (usually a bad one) into an external object, followed by identification with the external object that is now experienced by the infant as having been contaminated by the bad object. Splitting is the intrapsychic separation of the object into different partial objects. Typically, an unrealistically all-good (idealized) object and an equally unrealistically all-bad object are constructed. For Klein, the innate aggressive drive of the infant is central and the paranoid–schizoid position is viewed as a "normal" early psychosis from which the infant gradually emerges. In the course of normal development, in the presence of adequate parenting that provides the consistent availability of predominantly benign external objects, the cycle of projection and introjection gradually results in the introjection of more benign aspects of the external object (parent or other caretaker), and the bad internal object is gradually detoxified.

In the depressive position, infants, who have now developed the capacity to accept the existence of an external good object (for example, the nurturing breast of mother), are for the first time "grateful" to caretakers. However, this too presents a problem, for the infants now fear that their attacks on the giving object (which in the paranoid position they had felt justified in making) will damage the good object. This leads to infants' making efforts to repair the damage as well as to the emergence of self-directed aggression (guilt). Just as paranoid anxiety was central during the paranoid–schizoid position, depressive anxiety takes center stage during the depressive position. Infants now fear in the loss of caretakers. The depressive anxiety is defended against by denial and by a fantasy of being omnipotently able to restore the (idealized) good object. This is the "manic defense," for Klein a normal part of the depressive position in the second 6 months of life (Klein 1940).

Donald W. Winnicott
Donald W. Winnicott was both a practicing pediatrician and a psychoanalyst for most of his professional life. He worked with many categories of patients—including regressed adults, disturbed and delinquent adolescents, and problem children—and treated mother–infant–toddler pairs. Working with such a diverse population of patients, he experienced the deficiencies of both the libido and the structural theories. The libido theory focuses on drives and aggressive concepts; the structural theory concentrates on oedipal development and in Freud's formulation, places the "narcissistic neuroses" (i.e., the psychoses) in a separate group without a framework for treatment. Although he found the existing theories to be problematic, Winnicott attempted to fit his ideas within them. He handled his disagreements with Freud's ideas by reinterpreting them to meet his need to deal with highly disturbed early relationships. For example, he reworked the Oedipus complex to emphasize Klein's conflict between love and hate, rather than Freud's conflict between instinctual desires and fear of castration. (Winnicott acknowledged his debt to Klein, particularly with reference to the depressive position.) Another way in which Winnicott reinterpreted Freudian theory was to focus on the central function of an early maternal "holding environment." This primacy of early bonding contradicted Freud's concept of "primary narcissism," which held that the infant is at first not oriented toward others and that relationships become important only later, secondary to drive frustration. Winnicott simply changed Freud's meaning and said that what he really meant by primary narcissism was the state of early dependence on the mother.

Every individual, according to Winnicott, develops true and false selves. Insofar as the mother is empathically attuned in to her child, without intruding on the child, there is a core of feeling of wholeness and goodness from which the true self develops. With appropriate "mirroring," the child learns to play, to be creative, and to be alone with comfort. Those developmental achievements create the fundamental organizer, the true self (at times also called the ego by Winnicott). However, insofar as there is a mismatch in the relationship, the child's development is stunted, and the child develops a false self. In healthy people, the false self is relatively minimal. It is represented by politeness and social manners; however, in extreme states of illness, it may be the main self-representation. The genesis of such a severe pathological process is based on the seduction of the infant into complying with the imposed demands of the unempathic mother. The infant then develops false relationships; the child learns to live by imitating, becomes less spontaneous and creative, and is unable to play. A lifelong feeling of unreality and futility results. One positive function of the false self is that it protects the nascent true self from a damaging environment (Winnicott 1965, pp 140–152). Therapy of individuals with a dominant false self begins with accepting that self, and it proceeds through periods of negative transference and profound dependence toward a more full development and expression of the (previously hidden) true self.

Winnicott regarded psychoneuroses as grouped around defenses (especially repression), in contrast to psychoses, which result from annihilation anxiety and the breakdown of defenses. He believed that the breakdown has its roots in the original breakdown of "good enough" mothering and a consequent inadequate development of the true self. Winnicott (1965, pp 124–139) maintained that the psychoses are analyzable and that there is a gradation from normality through psychoneuroses and psychopathy to psychosis. However, psychotic patients do bring particular transference and countertransference problems to the analysis. Because
psychotic patients evoke annihilation anxiety in the analyst, countertransference hate is inevitable and is difficult to cope with, despite such compensations as being paid and being able to end the hour. These patients answer love by evoking hate; this is really a test to see whether the analyst can hate them “objectively.” The task of the analyst is to keep the hate latent, as the mother must when the infant frustrates her, until the patient has become healthier through the analytical process. The analyst must then tell the patient about the way the hatred had been evoked and how the analyst held it in abeyance until the patient was stronger (Winnicott 1947, pp 194–203).

Winnicott’s transitional object is a concrete, real external object (unlike the intrapsychic objects that we have been discussing). It is the infant’s first “not me” possession and is imbued with attributes of both mother and infant. The transitional object evolves out of activities occurring in the “space” between infant and mother. These activities generally have close links to the mouth or the mother’s body. For example, the child may at first put a fist or thumb in the mouth or stroke the corner of a blanket. The blanket gradually becomes special and essential to the child (the familiar security blanket). A stuffed toy such as teddy bear or even a hard toy may become a transitional object. This process is based on the facilitating, appropriate response of the mother. The blanket may become smelly, yet it must not be washed; and the teddy bear may become tattered, yet it must accompany the toddler everywhere. The evolution of the transitional object is the precursor of the child’s ability to play. As an intermediary object, the transitional object also serves as a precursor of the ability to be alone. There is wide variation as to when the transitional object develops, but it usually evolves from about 4 to 12 months (Winnicott 1971).

John Bowlby

Bowlby began his study of the attachment of children to their caregivers in the late 1940s. His work was contemporaneous with that of Spitz, who observed the profound depression produced in infants who were deprived of human contact (Spitz 1946). He came to differ with Spitz in his interpretation of the meaning of the observations, but their actual observations are highly consistent with each other. Bowlby collaborated initially with James Robertson in his naturalistic observations of young children who are separated from their mothers (much more briefly than the anaclitically depressed infants observed by Spitz) because of the mother’s hospitalization (Robertson and Bowlby 1952). The observations clearly confirmed that separation produced extreme distress in children and that there were significant long-term adverse effects on the children as a result of even relatively brief separations. These initial observations, combined with the fact that there was at the time no adequate theoretical framework for understanding the profound effects of separation, led Bowlby to research and formulate theories about attachment, separation reactions, related anxiety, depression, and psychopathological processes originating in disturbances in attachment.

Bowlby’s major thesis was that the child’s tie (attachment) to the object, for which he preferred the term attachment figure, is primary and instinctive (in the sense of instincts shared by humans and animals rather than in Freud’s sense of instinctual drives). This attachment is not secondary to the gratification of any drive. It is independent of the need for food and warmth and of any other striving. He strongly opposed the theoretical position that there is ever an early objectless state. Bowlby buttressed his argument with observations of nonhuman primates. He made the point that human infants are born in such a helpless state that the majority of the observable early attachment behavior must be on the part of the mother, whereas in some other primates, the baby is able to cling from the time it is born. In all primates, great distress is observed when mother and baby are separated, and the effects of separation are long-lasting, producing visible anxiety and a marked increase in clinging at ages when the clinging is decreasing in unseparated animals. He referred to the work of Harlow and Harlow (1962), whose experimental work on maternal deprivation in monkeys is now considered classic. Harlow’s observations supported Bowlby’s thesis that there is a primary need for clinging and contact. His motherless monkeys strongly preferred to cling to a soft cloth dummy mother that provided no nourishment than to a hard wire dummy mother that was equipped with a bottle of milk. In addition, monkeys raised without their mothers were highly abnormal in interaction with other monkeys later in life, despite the fact that their needs for nourishment, shelter, and warmth had been met.

Bowlby went on to extend his observations of attachment behaviors and responses to separation across various cultures, citing anthropological observations. “No form of behavior is accompanied by stronger feeling than is attachment behavior. The figures towards whom it is directed are loved and their advent is greeted with joy. So long as a child is in the unchallenged presence of a principal attachment-figure, or within easy reach, he feels secure. A threat of loss creates anxiety, and actual loss sorrow: both, moreover, are likely to arouse anger” (Bowlby 1969, p. 209). For Bowlby, the unpleasurable affects of anxiety, grief, and anger were secondary to the thwarting of attachment. His theoretical position was in many ways in keeping with the views of Winnicott, Fairbairn, and Guntrip.

Margaret Mahler

Mahler primarily used the libido theory’s drive model in describing the first few weeks of life, which are centered on achieving homeostasis and which she called the “normal autistic phase” (Mahler et al. 1975). According to Mahler, the newborn does not differentiate internal from external stimuli; there is only tension and satiation. By the second month, the infant begins the “normal symbiotic phase,” in which there is a relationship characterized by an “omnipotent fusion,” a “delusion of a common boundary” with “the need-satisfying object.” From the infant’s perspective, mother and child are a “dual unity.” If the symbiotic period progresses normally, the infant begins to develop “memory islands” and a “core sense of self,” which are preparatory for the “hatching” that will occur at about 5 months. In her description of this period, Mahler used the concepts of libido theory but also referred to both Rene Spitz’s observations of the first months of life and to Winnicott’s concept of the holding environment.

What follows these earliest months, the period from about 5 months to beyond 3 years, is termed “the psychological birth of the human infant” by Mahler. During this time,
the stages of the separation—individuation process occur. Mahler formulated a series of subphases of this process. In summary, the subphases are the following:

1. **Differentiation**: 4 to 8 or 9 months. During these months, there is the “first tentative” pushing away from “completely passive lap-babyhood.” The 5- to 6-month-old infant gradually begins to creep. During this time, transitional objects develop (a term coined by Winnicott and discussed earlier in this section). The infant soon begins differentiating, with more or less anxiety, the faces of strangers from primary caretakers.

2. **Practicing**
   a. **Early**: 7 months to about 1 year. This subphase overlaps with differentiation. Infants begin to crawl and stand. They become upset if they end up too far away, frequently paddling back to mother for “emotional refueling.”
   b. **Practicing subphase proper**: about 12–18 months. This subphase begins with walking and ushers in a “love affair with the world.” The children are frequently elated, curious, and adventurous. They are delightful to observe but must be carefully watched because they are likely to dash blithely into precarious situations. They tend to be impervious to minor falls and other mishaps.

3. **Rapprochement**: gradually, from about 15 to 22 months or more, the carefree behavior gives way to anxiety about separation and fear of “object loss.” The toddler is learning that “the world is not his oyster” (Mahler et al. 1975, p. 78). The child alternates between demanding, negativistic, challenging behavior, and seeking love and approval by “wooing” behavior.

4. “The child on the way to object constancy”: 24 months to 3 years and beyond.

Mahler was careful to blur the boundaries of each of the subphases. She stated that for all of our lives, we are “both fully ‘in’ and at the same time basically separate from the world ‘out there’” (Mahler et al. 1975, p 3). The optimal unfolding of phases depends on the emotional availability of the mothering person. If it is disrupted in the earliest months, the result can be the development of an infantile psychosis either because of lack of maternal availability or empathy or because, for constitutional reasons, the infant is unable to respond to the mothering. Regardless of whether the cause is environmental or constitutional, if the symbiotic mother—infant relationship fails to provide safe “anchoring” or discourages hatching, the separation—individualization process cannot proceed normally. Later phases may also be disrupted, for example, by overprotective mothering, which inhibits independence, or because of precocious motor development, which may lead the infant to separate physically from the mother before psychological readiness for that degree of separation. In addition, Mahler (1972, p. 494) stated that the success or failure of the rapprochement subphase lays “the foundation for subsequent relatively stable mental health or borderline pathology.”

**Otto Kernberg**

Otto Kernberg believed that it is possible to integrate an ego psychological approach to the understanding of mental functioning with an objects relations perspective. His major contributions have stemmed from his work on the psychoanalysis and psychotherapeutic treatment of patients with severe character disorders, particularly those with borderline personality organization, as well as patients with narcissistic character (Kernberg 1984). This section summarizes his contributions to object relations theory.

The primitive defenses of splitting and projective identification, first described by Klein, are central to the diagnosis of borderline personality disorder as conceived by Kernberg. Kernberg’s depiction of the inner world of borderline and psychotic patients is, however, uniquely his own. Splitting breaks up the internal representation of objects and of the self into part object representations, each with an associated affect. Thus, objects are perceived as either all good or all bad in relationship to the self. Projective identification, first conceptualized by Klein (1937) as a primitive defense of the paranoid–schizoid position (see section on Klein), was further elaborated by Kernberg. The central feature of projective identification, according to Kernberg, is that projective identification which always involves the projection of an internal object relation with its associated affect. When projection is effective, the subject eliminates the unacceptable impulse or idea from any connection with the self. In contrast, in projective identification, the connection to the unacceptable contents is preserved along with the tie between the part self and the part object. The connection cannot be totally eliminated.

Kernberg envisioned the inner world of the borderline or psychotic patient as being populated by numerous unintegrated part self-part object dyads that are each linked by a predominant affect. These internal nuclei are kept separate by the defense of splitting. The borderline individual projects these pathological inner contents onto any significant other with whom he or she interacts. Which of these self-object-affect structures is active can shift from moment to moment; this results in the chaotic and shifting pattern of relationships that is the essence of what is observed clinically in patients with borderline psychopathological disorders (who can be described as being stably unstable). Depending on what happens in the course of an interaction, the relationship between the patient and other can shift rapidly, for example, from that of the good nurturing mother interacting with the blissfully nursing infant with a sense of mutual pleasure, to that of the rageful depriving mother interacting with the rageful deprived infant. Such a shift can occur instantaneously in the course of an interview if the interviewer does something that is perceived by the patient as being depriving or attacking.

**Erik H. Erikson**

Erikson, a psychoanalyst and integrative theoretician, contributed to psychoanalytic theory and to the practice of American psychiatry. He divided the entire life cycle into eight stages, thus extending into adulthood Freud’s notion of infantile psychosexual stages while at the same time broadening Anna Freud’s concept of the developmental lines of childhood. Erikson (1959) considered each stage of psychological development to have its own critical developmental task. Furthermore, he believed that the achievements and failures of earlier stages influence later stages, whereas later stages modify and transform earlier ones. As shown
in Table 28–11, Erikson (1982) linked each *psychosexual* stage to a particular body zone or zones. In each stage, the individual negotiates a phase-specific *psychosocial* developmental task toward the achievement of specific strengths. In this model, each individual evolves a mode of interpersonal and intrapsychic functioning with emergent social capacities uniquely adapted to a particular social milieu. The “crises” of each stage are normative, not pathological ones, and the developmental tasks are never fully resolved in each stage but continue to be worked out throughout the life span.

To simplify, life begins with the oral-sensory stage of infancy, marked by the potential development of what Erikson called basic trust aiming toward the achievement of a sense of hope. In early childhood, the second or anal-muscular stage, the toddler struggles with the task of developing a sense of autonomy aiming toward the capacity for strength of will. Relative degrees of failure at this stage may predispose the child to shame and doubt. Next, Erikson’s play age, coinciding with the nursery school-age or preschool-age child, is marked by the genital-locomotor stage or third stage of development. Here the child’s task is to develop a sense of initiative as opposed to further shame or guilt. The lasting achievement of this stage is a sense of purpose. In the fourth stage, the school-age child, in what is traditionally called the stage of latency, tries to master the crisis of industry versus inferiority aiming toward the development of a sense of competence. At puberty, the fifth stage, the task of adolescence is to navigate the familiar “identity crisis” (see later) as each individual struggles with a degree of “identity confusion.” The lasting outcome of this stage can be a capacity for fidelity. Young adulthood, at the stage of genitality or sixth stage, is marked by the crisis of intimacy versus isolation, out of which may come the achievement of a capacity for love. In the procreative period of adulthood, the seventh stage, the individual may develop a capacity for generativity at the risk of stagnation. Out of this struggle comes the ability to care. Finally, Erikson viewed the wisdom of old age, the eighth stage, as a summation of all the achievements of the previous seven stages. Similarly, he considered that all of the modes of functioning in the previous psychosexual stages come into play at this stage. Hence, the task of old age is to develop a sense of integrity at the risk of despair.

### Self-Psychology

Within psychoanalysis, Freud (1911b) posited that psychological investment in the self (narcissism) antedated and always remained more important than interest in others or the external world. Heinz Kohut (1971) held that the meaning of self could be empathically comprehended. He viewed empathic comprehension as the fundamental mode of psychoanalytic investigation (Kohut 1959). It is the knowledge of the other’s experience, what it is like to be in that person’s shoes. Empathy is the understanding of another’s complex psychological experience as whole. He used the term self to refer to a center of initiative, experience, or the core of personal being. Kohut largely ignored the long history of the idea of self in religion, philosophy, and psychology. He did not address the conceptual complexities that result from attempts to be more precise about the ideal (Meissner 1986) or the evidence that the self-experience varies dramatically across cultures. Like Freud (1905a, 1905b), who claimed that the sexual quality of experience was immediately apparent, Kohut claimed the self-experience was directly knowable to us all. Many other authors have addressed the question of the meaning of the self. They have put forward such ideas as the continuing experience of one’s affective responses (Emde 1983) or the sense of that which absolutely belongs to one (Goldberg 1983).

Kohut’s singular contribution was the idea of the self-object. Clinical observations led him to believe that the self could survive and prosper only in the context of experience with others. These clinical experiences find support by observations of infants and young children that consistently show that appropriate psychological interactions with others are essential for early psychological development (Stern 1985). These experiences Kohut called self-objects, that is, objects (in the psychoanalytic sense of intrapsychic representation of other people) that are necessary for the well-being of the self. Kohut was speaking of intrapsychic experiences, not interpersonal relations. Intrapsychic experience may be contingent on interpersonal events. Self-objects remain essential throughout life. Contrary to psychoanalytic theories like Mahler’s that characterize maturity in terms of autonomy (Mahler 1975) self-psychology views mature people as ordinarily dependent on others for appreciation, comradeship, meaning, and solace.

The study of self-psychology began with the realization that many symptoms of psychological distress could be understood as arising from disorders of the self. These include symptoms involving direct experiences of an endangered, enfeebled, or fragmented self; and symptoms arising from unsatisfactory attempts to protect an endangered self. Sometimes the symptoms of self-pathology are acute, but more often they are chronic states whose intensity varies as the self is felt to be more or less in danger. Examples of these symptoms include certain depressive states, traumatic states, hypochondriasis, some forms of rage, and direct experiences of profound disorganization. Many symptoms are understandable as attempts to repair an impaired or endangered self. These include relations with

others designed to achieve urgently needed self-object experiences and activities designed to soothe or stimulate the self.

When development goes well, self-objects ensure that the painful experiences of living are not overwhelming. The child may experience painful and distressing events but not to such an extent that the capacity to maintain a cohesive and vigorous sense of self is threatened. Responsive self-objects maintain a milieu in which the child feels safe, appreciated, and able to comfortably idealize others in a developmentally appropriate way. The environment empathically comprehends and supports the child (Stern 1985). In such an environment, the child thrives. She or he can increasingly maintain self-object functions that were performed by others in their physical absence.

Several types of self-object failures seem to lead to later disorders of the self. Early deprivation of human responsiveness is psychologically and physically devastating to infants (Spitz 1945). Less severe deprivations may result in serious lack of adequate experiences with caretaking self-objects. For example, children of depressed mothers do not receive ordinary enthusiastic responsiveness, engagement, and mirroring (Cohler 1984, Radke-Yarrow et al. 1985). Many difficulties in life may deprive a child of needed self-object experiences. These include loss of a parent, parents who are psychologically unavailable because of personal pathologic processes or life circumstances, caretakers who are made anxious by and therefore avoid developmentally appropriate demands (e.g., for the opportunity to idealize), and caretakers deficient in empathy who do not comprehend the child’s developmental needs.

Relational Perspective, Interpersonal Psychoanalysis, Social Constructivism, and Intersubjectivity

Relational Perspective

There is a momentum in contemporary psychoanalytic writing toward the full appreciation that the analyst’s personal involvement in the analytic process is both inevitable and useful (Mitchell 1988b, Hoffman 1992b, Renik 1993a, Gill 1994, Hoffman 1994, Roughton 1994). This relational perspective does not constitute a new psychoanalytic theory but, in fact, links together loosely a wide range of theoretical models, including interpersonal psychoanalysis, British object relations theory, self-psychology, intersubjectivity, and social constructivism. The relational perspective addresses a different understanding of the role of the analyst as well as different ways of thinking about the basic motivational forces in human development.

This cluster of otherwise diverse and often competing theories has in common a greater emphasis on the actual here-and-now interaction between analyst and analysand, whether this is viewed in interpersonal or intrapsychic terms. It encompasses the participant observation of the interpersonalists, the projective identification and transference-countertransference focus of the British object relationists, the empathic immersion and self-object phenomena of the self psychologists, the analyst’s stance within the observational field of the intersubjectivists, and the social constructivists’ emphasis on the effect of the analyst’s personal emotional presence on the analysand’s experience.

These theoretical perspectives also have in common a deep emphasis of Freud’s drive theory as the basic motivational force and a greater emphasis on some version of the idea that the human organism seeks attachment and relations with others, not just drive discharge, as a basic motivational system. In this relational perspective, the individual as a separate entity is not the basic unit of study. Rather, the focus is on the interactional field, whether as mother-infant or analyst-ana lysand (Mitchell 1988b).

The dividing line between this relational perspective and the work of some contemporary classical analysts is less than sharp and clear, particularly in the clinical interchange. As in most psychoanalytic controversies, theoretical explanations tend to sharpen conceptual differences, even when clinical practice reveals much similarity and overlap in what is actually said and done. Some writers, Winnicott and Loewald, for example, continued to use the terms drive and instinct but expanded their meanings to include a relational perspective. Loewald (1978) redefined instinct not as an innate given but as developing out of interactions between the infant and the infant’s human environment. Although they may differ in degree and in balance, drive theorists and relational theories agree—as Freud himself repeatedly stressed—that both innate and experiential factors are influential, and it seems more useful to view the two stances as dialectical rather than as dichotomous.

Nevertheless, there are significant differences of emphasis, and certain points are more easily clarified by highlighting the contrasting points of view. The more rigorously analysts adhere to classical theory, the more they will work from the perspective of a one-person psychology, in which the locus of the psychoanalytic process is within the analysand’s mind and in which everything is understood through the prism of intrapsychic compromise formation, unconscious fantasy, and psychic reality. Resistance and transference are the unfolding of the analysand’s inner world in this new analytical setting, in which repetition of old experiences and response patterns is fostered, and the interpretive focus is on intrapsychic defensive operations that interfere with free association. The actual persona and the person and the behavior of the analyst are considered less important in determining the nature of transference and resistance. The analyst’s position outside the observational field is thought to allow a more objective perspective from which to make confident interpretations of the analysand’s intrapsychic experience and to monitor the analyst’s own countertransference reactions that might have a negative impact on the interpretive work.

However, there has been an evolution of thinking among many analysts on these issues, so that differences between classical and relational perspectives are less striking than when each is presented in its most defining form. Many analysts may still accept the basic tenets of classical theory yet incorporate a degree of relational perspective in their clinical writing and may, for example, work comfortably within a clinical perspective that focuses on the here-and-now in the transference (Gill 1982), that recognizes countertransference as an ongoing source of data (Jacobs 1986), and that considers enactments to be inevitable and to provide useful insight (Chused 1991, McLaughlin 1991, Renik 1993a, Roughton 1994).

Nevertheless, the relational perspective is defined by its much greater emphasis on a two-person psychology, both...
in the developing individual and in the clinical experience (Bachant and Richards 1993). The infant and the analysand both seek contact and interaction. Development and therapeutic effect both are seen as mediated through relationships. The locus of the psychoanalytic process is the interactive field of the two persons, even though the primary purpose is the understanding of the inner world of the analysand. As such, there is a tilt toward viewing the analytical relationship more in interpersonal terms rather than solely through the prism of the analysand’s intrapsychic experience. Analysts are more likely to use their acknowledged subjectivity as a tool than to distance themselves behind a presumed objectivity. Transference is more often interpreted in its immediate manifest response to the actual person and behavior of the analyst than as a distorted perception of a neutral, objective analyst. Although interpretation and insight are still considered essential aspects of the analysand process, the therapeutic effects of the relationship are accorded a more prominent place.

Object relations, self psychology, and intersubjectivity are discussed elsewhere; the remainder of this section concentrates on interpersonal psychoanalysis and social constructivism as important embodiments of the relational perspective.

**Interpersonal Psychoanalysis**

In the late 1970s, a divergent approach to psychoanalytic theory and practice began to coalesce in the work of Harry Stack Sullivan, Erich Fromm, Frieda Fromm-Reichmann, and Karen Horney around some commonly held assumptions. They shared the belief that classical drive theory was fundamentally flawed and that Freudian theory underestimated social and cultural influences in explaining normal and pathological developments of personality. In discounting drive theory and emphasizing cultural influences, these analysts have often been misunderstood as having a “sociological” view of the individual as molded passively by the environment; their clinical work has been criticized as being superficial and ignoring passions and deeper conflicts. As Greenberg and Mitchell (1983) pointed out, however, this is a serious misreading of their work. Deep, intense passions and conflicts are not ignored, but these analysts rejected the idea that they arise as derivatives of instinctual drives. Rather, they see passion and conflict arising in the relationships with others, whether real or imagined.

At about the same time that this interpersonal tradition was developing in the United States, another major contribution to the shift from a drive model to a relational model came from W. R. D. Fairbairn in Edinburgh, working in relative isolation from his Kleinian colleagues in England. Unlike Sullivan, Fairbairn did not emphasize cultural factors so much as challenge the basic understanding of libido theory and assumptions about psychosexual development. Still working within the Freudian framework, he sought to redefine the basic motivational principle of libido not as pleasure seeking but as object seeking. Fairbairn, like others who are now identified under the umbrella of the relational perspective, saw the human experience as a search for contact and attachment, not as a set of instinctual tensions seeking release (Greenberg and Mitchell 1983).

Fairbairn had an important influence on British object relations theory and deserves recognition, along with Sullivan, as one of the seminal thinkers in what has lately been characterized as the relational perspective. It would not be correct, however, to identify him with interpersonal psychoanalysis, which is the movement that diverged sharply from classical psychoanalysis under the influence of Sullivan and those who followed him in the United States.

Sullivan introduced the term **interpersonal** in 1927, and it is his name that has been most closely identified with that perspective. He saw the human mind as inherently dyadic and from earliest infancy in constant responsive interaction with its caretakers. Research on infants supports such a view (Stern 1985). Although the terms interpersonal and intrapsychic have come to represent a dichotomy in much of psychoanalytic discourse, Sullivan did not reject the concepts associated with the intrapsychic perspective so much as object to the exclusion of the interpersonal from the classical perspective. What he did uncompromisingly oppose was drive theory because, as understood at that time, the drives as the primary motive force arose independently in the id and were sheltered from the interpersonal field. As Mitchell (1988a) has pointed out, the concept of drive has been increasingly “interpersonalized” in later theoretical developments, so that contemporary interpersonalists find the concept less objectionable.

Sullivan was not an integrative theorist or a compelling writer in the ways that Freud was. In addition, he was not a rebel from orthodox psychoanalysis, as were other innovators. He came from the world of general psychiatry with a talent for working with patients suffering from schizophrenia in an operationalist methodology, and he tended not to use the language of psychoanalysis but to develop his own nomenclature. These factors, apart from the perceived merit of his ideas, have made him less known to more traditional psychoanalysts. Even some contemporary interpersonalists believe that Sullivan’s theories lacked a sufficient conception of the inner world (Mitchell 1988a). For example, he explained mental disorder as the result of inadequate interpersonal communication due to the interfering effect of anxiety (Levenson 1983). Those who have studied his work stress that what sounds naïve in his explanations is nevertheless grounded in a depth understanding of the human condition and a respect for the uniqueness of the individual, and this allowed him to be uncommonly effective with patients. These therapeutic principles have endured and are now finding new credibility in the current interest in the relational perspective. More in-depth study of Sullivan’s ideas and of interpersonal psychoanalysis than can be presented here is recommended for those interested (Sullivan 1953 and 1956, Guntrip 1961, Mullahy 1970, Greenberg and Mitchell 1983, Levenson 1983, Antonovsky 1987, Mitchell 1988a).

**Social Constructivism**

Hoffman (1983, 1991, 1992a, 1992b, 1994) has introduced a new paradigm for understanding the psychoanalytic situation, which he calls social constructivism. The “social” part of the term refers to the analyst’s personal presence and involvement in the analytical situation, and thus it is linked to the interpersonal and the relational perspectives. However, Hoffman emphasized that beyond the shift from drive to relational issues of those perspectives, his new paradigm proclaims a shift from a positivist to a
constructivist model as well. That is, not only is the analyst personally involved in the analytical situation, but personal involvement is wedded to the construction of meaning for the patient, because the analyst’s understanding is always a function of her or his perspective at any given moment. In Hoffman’s view, the analyst is continually implicated in “constructing” the patient’s experience, and not to attend to that aspect of the analytical relationship is to miss the vital issue.

Constructivism generally refers to the concept that meanings are generated, as texts are interpreted, rather than there being one true meaning awaiting discovery. Hoffman’s social constructivism goes further. It is not simply an interpreting of reality but a shaping of it through the mutual and reciprocal influences in the interpersonal analytical relationship. He also contrasted his view with the constructivism of Schafer (1983), which he described as concerned primarily with the effect that the analyst’s theoretical bias or occasional countertransference has on the way the analysand’s story emerges. Hoffman objected to Schafer’s view of countertransference as occasional and undesirable and to be overcome. He wanted to free analysts to be themselves and to speak their minds, constrained only by the purposes of the analysis (Hoffman 1992a, 1992b, 1994).

Lest this sound like casting off all knowledge and previous experience in favor of uncharted spontaneity, Hoffman (1992b) was quick to assure his readers that he was advocating a subtle diminishing of the authority of theory in favor of a subtle increase in respect for the analyst’s awareness of and use of personal subjective experience in guiding what he or she does and says. Subjective experience, for both analyst and analysand, is a continuous stream, only a small fraction of what can be attended to at any given moment. What is selected from that stream of experience is influenced by the unconscious determinants what include the patient’s transference and the analyst’s countertransference. Hoffman’s point is that it is impossible to avoid the analyst’s influence in this subtle selection. Therefore, rather than attempting to control subjectivity and remain outside the action, analysts should feel free in their subjectivity and embrace the uncertainty of this freedom (1992a).

Hoffman made the point that patients are extremely sensitive to certain facets of their analysts’ ambiguous responses to them. What is often called distortion in the transference is instead a highly selective attention to something present in the analyst, sometime that one patient notices but another will ignore (Hoffman 1983). As Racker (1968) has said, interpreting the transference fully means being receptive to the patient’s interpretation of the countertransference.

Hoffman (1992b, p 302) was careful to place these innovations within a firm psychoanalytic frame, and he detailed its features, which include “a circumscribed time and place; the asymmetry of personal expression in the process; a primary interest in exploring the patient’s experience, a commitment by the analyst to critical reflection on his or her own participation; and a sense of the relationship as a whole as a means of promoting the patient’s development. Every interaction in this context is experienced by the analyst as a psychoanalytic interaction. There are no exceptions. . . . the stamp of the analytic situation should never be lost on the participants.”

Social constructivism is Hoffman’s term, and it is his paper that most fully explore these concepts. Nonetheless, Gill’s contribution to this concept must also be acknowledged, as Hoffman carefully does. Through a series of works in the past 15 years, Gill’s thinking about transference and mutual influence and constructivism has evolved in this direction, although he may not have gone as far as Hoffman. Gills (1994, p 156) view of transference is “the analysand’s plausible experience of the relationship. It is based on the contributions of both participants to the here-and-now interaction as well as on their respective past experiences.” Countertransference is defined similarly as based on contributions of both participants in present interaction and from past experiences. Although Gill kept his roots in classical theory, he adopted a constructivist perspective, and he insisted that psychoanalysis is both a one-person and a two-person psychology, that the innate and experiential are always working together, and that the analytical situation is a continuing interaction between two participants that must be the subject of a mutual exploration (Gill 1994).

**Intersubjectivity**

Intersubjectivity in psychoanalysis refers to the dynamic interplay between the analyst’s and the patient’s subjective experiences in the clinical situation. To some extent, all schools of psychoanalysis agree on the significance of intersubjectivity in psychoanalytic work. However, in the current psychoanalytic literature, the concept of intersubjectivity constitutes a major epistemological and clinical challenge to the “classical” paradigm, which is grounded in the positivist scientific orientation. Intersubjectivity embodies the notion that the very formation of the therapeutic process is derived from an inextricably intertwined mixture of the clinical participants’ subjective reactions to one another. Knowledge of the patient’s psychology is considered contextual and idiosyncratic to the particular clinical interaction. This interaction nexus is considered the primary force of the psychoanalytic treatment process.

The intersubjective position is that mental phenomena cannot be sufficiently understood if approached as an entity that exists “within” the patient’s mind, conceptually isolated from the social matrix from which it emerges. Intersubjectivists see the analyst and the patient together constructing the clinical data from the interaction of both members’ particular psychic qualities and subjective realities. The analyst’s perceptions of the patient’s psychology are always shaped by the analyst’s subjectivity. Conversely, the patient’s psychology is not conceptualized as something discoverable by the external, unbiased observer (Hoffman 1991, Ogden 1992a, 1992b, Spezzano 1993, Ogden 1994).

**Conclusion and the Future**

Over a hundred years ago, Freud began his investigation into the human psyche, and there have been many additions and revisions to his theories of mental life, as was laid out in this chapter. Increasingly, the discipline of psychoanalysis is confronted with new knowledge from neuroscience and with the need for empirical research to ground psychoanalysis in the sciences. This may lead to revisions of long-held theories within psychoanalysis, but may also give a biological basis for psychoanalysis as well (Olds 2006). For example, the discovery of mirror neurons in monkeys
(Rizzolatti and Arbib 1998) gives a biological basis for identification and projective identification, two major theories in psychoanalysis. When a monkey picks up a morsel of food and puts it in its mouth, there is a particular pattern on EEG, in the premotor cortex, which coordinates this activity. They discovered that a motionless monkey watching this activity has the same pattern in its premotor cortex. This is the basic concept of mirror neurons. This same phenomenon has been shown for human affect. The person observing the affect of another will have the same brain activity. As this example demonstrates, this exciting dialogue between psychoanalysis and other sciences can bring new understanding of mental life and inform psychoanalytic theory, just as psychoanalysis can contribute to knowledge in other sciences.

Glossary of Psychoanalytic Terms*

**Abreaction**
The discharge of affect associated with a traumatic memory. Abreaction may be brought about by hypnosis or free association.

**Adaptive point of view**
A metapsychological framework that considers how the developing mind is influenced by environmental realities. In this model, the ego is thought of as the “organ” of adaptation.

**Aggressive drive**
One of the primary instinctual drives, aggression includes the urge to harm or destroy, the urge to dominate or prevail over others, and strivings toward mastery. The aggressive drive is a major source of intrapsychic conflict.

**Anal**
Stage of psychosocial development from about 18 months to 3 years during which pleasures and conflicts center on defecation and urination and their symbolic derivatives. In addition, which increased cognitive and motor development, issues of mastery, autonomy, obedience, and defiance are observed.

**Cathect**
The attachment of mental energy to a thought or memory, resulting in an increased emotional or motivational intensity associated with the thought or memory.

**Character (personality) disorder**
Habitually and generally inflexible patterns or behaviors that are ego-syntonic, that is, cause little subjective discomfort and are experienced as appropriate, reasonable, and justified. Such behavior may actually cause problems in adaptive functioning and interpersonal relationships.

*Source: Abstracted from Moore and Fine (1990)
| **Compromise formation** | An activity of the ego that attempts to solve conflicts between opposing forces operating in the mind, in particular the gratification of instinctual wishes that are prohibited by the superego or by reality. Compromises may take many forms, including character traits, neurotic symptoms, dreams, and fantasies, adaptive behavior, and transference. |
| **Conscious** | The portion of mental activity and content that is directly available to immediate perception (as opposed to unconscious or preconscious). Conscious mention obeys rational, secondary process logic. |
| **Countertransference** | Attitudes and feelings of the psychiatrist toward the patient. As narrowly defined, countertransference comes about as a result of activation of wishes, fantasies, or conflicts from the psychiatrist’s life. More broadly defined, countertransference also includes reactions to the patient’s projections or role enactments. Countertransference responses have the potential to have a negative impact on the therapeutic approach to the patient and also to provide data about unconscious processes occurring in patient and psychiatrist. |
| **Defense mechanism** | Specific unconscious operations used by the ego to protect against the fantasied danger associated with conscious awareness or unconscious wishes. Examples include repression, displacement, reaction formation, projection, isolation, and undoing. |
| **Depressive position** | In Kleinian theory, a constellation of internal object relations, defenses, and anxieties in which others are viewed ambivalently (as containing both goodness and badness, as opposed to the split objects of the paranoid–schizoid position) and in which fear and guilt are felt around the fantasy that one’s aggressive impulses may destroy the needed and love object. |
| **Developmental point of view** | Metapsychological perspective that emphasizes the progressive unfolding of stages of development and focuses on the contribution of childhood experience to the psychology of the adult. |
| **Dynamic motivational point of view** | Metapsychological perspectives that considers the actions of mental forces (wishes or needs inherent in the nature of humans), which may be in opposition to one another, resulting in conflict and compromise. |
| **Dynamic unconscious** | The content and processes of the system, which unconscious are kept outside conscious awareness by repression. |
| **Ego** | In structural model, the mental agency that is positioned between the physiologically based instinctual urges and the outer world. Its functions include mediating between the pressures of the id, superego, and reality and the variety of processes or perception, cognition, memory, motor behavior, and learning. |
| **Ego ideal** | The portion of superego functions that includes goals, ideals, and standard of thought and behavior. It is involved in the experience of self-esteem, pride, and shame. |
| **Empathy** | A mode of knowing or perceiving the emotional or psychological state of another, in which the quality of experience of one person in momentarily shared by another. |
| **Envy** | A primitive emotion of desire, of wanting what the other has, combined with a hostile wish to destroy or spoil the source of that which is desired. |
| **Fixation** | The persistence of modes of gratifying impulses, reacting defensively to perceived danger, and relating to objects that belong to earlier stages of psychosexual development. Points of fixation can be returned to in the process of regression. |
| **Free association** | The basic activity in psychoanalytic treatment in which the patient reports everything that comes to mind without the usual selectiveness used in conventional discourse. |
| **Id** | In the structural model, the collection of unconscious drives and drive derivatives that continually push for gratification. |
| **Insight** | The conscious recognition and comprehension of previously unconscious mental content and conflicts, as occurs during psychoanalytic treatment. Insight is typically accompanied by adaptive behavioral changes. |
| **Instinctual drives** | Innate motivational forces originating within the organism that seek discharge or gratification. In Freud’s theory, drives are characterized by their source, aim, and object. The two basis instincts are the sexual and the aggressive. |
| **Internalization** | A process by which aspects and functions of need-gratifying relationships are taken into the self and represented its psychic structure. Types of internalization include incorporation, introjection, and identification. |
Interpretation

The principle type of therapeutic intervention in psychoanalytic treatment that brings to the patient's attention observations about his or her mental processes and their underlying motives, conflicts, compromises, wishes, needs, and patterns of object relations. The expected outcome of interpretation is insight, psychic structural change, and symptomatic improvement.

Latency

Stage of psychosexual development between the approximate ages of 5 and 12 years in which the sexual drives and conflicts are less apparent and the major activities of the child are learning and other social approved channels of gratification.

Libido

Term originally used to refer to sexual desire but later used by Freud to describe the metapsychological concept of mental “energy” that could be deployed toward and attached to various mental representations or psychic structures.

Metapsychology

An abstract conceptual framework used to organize, systematize, and orient clinical observations.

Narcissism

In its original use, narcissism refers to self-love, but the term was elaborated theoretically by Freud to refer to the libidinal cathexis of the self (or ego). In modern theory, aspects of character organization, self-experience, affect regulation, and object relations are discussed along the dimension of normal versus pathological narcissism.

Neurosis

A set of psychiatric syndromes characterized by abnormalities of emotions, attitudes, behavior, and thought and that have in common (in psychoanalytic theory) their origins in unconscious psychic conflict. Classic neuroses include hysteria, obsessions, phobias, and certain types of neurosis are ego-dystonic, that is, are recognized by the patient as abnormal and alien to the self.

Object

As defined by Freud, a person or thing through which instinctual needs can be gratified. The inner mental schemas or constructions that conceptualize other persons are referred to as object representations. The theory of object relations examines the relationship of the self to internal objects and the interpersonal enactments of those mental phenomena.

Object constancy

A developmental achievement in which mental representations of love objects are experienced as constant and stable, despite their availability or unavailability.

Oral

The stage of psychosexual development occurring in the first 18 months of life, during which the oral and perioral areas provide the major source of sensual pleasure. Because the infant is extremely dependent during this stage, optimal development requires considerable parental attunement to the needs of the infant; if this is provided satisfactorily, the infant should acquire a sense of trust and a sense that the world is safe and that the infant’s needs will be met.

Paranoid–schizoid position

In Kleinian theory, the earliest and most primitive mental organization, in which there is a predominance of the defenses of projective identification, splitting, primitive denial, and idealization. During moments of frustration in this stage, there is the experience of diffuse rage and persecutory anxiety.

Phallic–oedipal

Stage of psychosexual development for approximately 3–6 years of age, during which the genitals become the major source of sensual pleasure. During this stage, the child develops an intense desire to possess exclusively the parent of the opposite sex and to eliminate the other parent who is perceived as a rival. The jealous conflict of this triangular relationship, with accompanying fantasies of retaliation by castration, leads eventually to identification with the parents and the development of the superego.

Pleasure–unpleasure principle

The tendency of the mental apparatus to seek pleasure and avoid principle unpleasure. According to Freud's libido theory, pleasure is attained through drive discharge, and unpleasure represents the buildup of undischarged mental energy.

Preconscious

In the topographical theory, mental content and processes that are not conscious but can be readily accessed by the direction of attention.

Primary process

Type of mentation associated with the unconscious, characterized by irrationality and a predominant emphasis on wish fulfillment and drive discharge. Primary process logic involves many of the mechanisms and qualities seen in dreams, including symbolization, displacement, condensation, absence of negatives, and timelessness.

Psychic determinism

A central idea of psychoanalysis, which asserts that all psychological events are influenced and shaped by past experiences that nothing in mental life occurs solely by chance.

<tr>
<td><strong>Regression</strong></td>
<td>A shift in the organization of mental functioning to a more developmentally immature level, often occurring defensively in the context of anxiety associated with higher level functioning but also seen in sleep and dreaming, love and sex, esthetic and religious experiences, and psychoanalytic treatment.</td>
</tr>
<tr>
<td><strong>Repetition compulsion</strong></td>
<td>A controversial concept that descriptively refers to the tendency to repeat certain distressing or painful experiences during the course of life; also referred to as the neurosis of destiny.</td>
</tr>
<tr>
<td><strong>Resistance</strong></td>
<td>The opposition to free association and other aspects of participation in psychoanalytic treatment, activated to prevent the emergence of unconscious wishes and their associated anxieties.</td>
</tr>
<tr>
<td><strong>Secondary process</strong></td>
<td>Rational, logical, linear, controlled thought that characterizes conscious mentation and follows the rules of Aristotelian logic.</td>
</tr>
<tr>
<td><strong>Self</strong></td>
<td>The total person including the body and the psychic organization; the center of subjectivity; the nuclear core of the personality.</td>
</tr>
<tr>
<td><strong>Self-object</strong></td>
<td>In self-psychology as developed by Kohut, objects who provide an interpersonal function that optimally contributes to the maintenance of cohesive self-experience (e.g., mirroring or idealizability).</td>
</tr>
<tr>
<td><strong>Separation-individuation</strong></td>
<td>Developmental process elaborated by Mahler in which the infant progressively emerges from the symbiotic unity with mother and forms a sense of individual selfhood and a sense of differentiation from love objects. The subphases of this process include “hatching” (differentiation), practicing, rapprochement, and “on the way to object constancy.”</td>
</tr>
<tr>
<td><strong>Structural model</strong></td>
<td>Also known as the tripartite mode, Freud’s later model of the mind that divides the mind into three structures: id, ego, and superego.</td>
</tr>
<tr>
<td><strong>Superego</strong></td>
<td>Mental structure that includes the functions of moral standards, ideals, prohibitions, and conscience, and generates the affect of guilt and shame.</td>
</tr>
<tr>
<td><strong>Therapeutic alliance</strong></td>
<td>The rational, conscious relationship between patient and psychiatrist based on the mutual agreement to work together cooperatively for the patient’s benefit.</td>
</tr>
<tr>
<td><strong>Topographical model</strong></td>
<td>Freud’s first systematic model of the mind classifying three regions of mental functioning: conscious, preconscious, and unconscious.</td>
</tr>
<tr>
<td><strong>Transference</strong></td>
<td>The unconscious displacement of feelings, attitudes, and expectation from important persons of childhood onto the person of the analyst or the analytic relationship.</td>
</tr>
<tr>
<td><strong>Unconscious</strong></td>
<td>Set of mental processes and content that operates outside conscious awareness. Unconscious mentation tends to be irrational, obeys primary process logic; and may be revealed through dreams, parapraxes, and free associations.</td>

Manifestations and Assessments of Psychiatric Illness
Psychopathology is the study of the nature and causes of mental disorders. Because definitive etiologies for most mental disorders have not been identified, psychopathology for the most part is focused on the myriad manifestations of psychiatric illness. An elusive concept itself, mental disorder has been defined in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) (American Psychiatric Association 2000, p. xxxi) as “a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress (e.g., a painful symptom) or disability (i.e., impairment in one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom.”

The manifestations of psychiatric illness can be grouped into five broad domains of human functioning: (1) consciousness, orientation, memory, and intellect; (2) speech, thinking, perception, and self-experience; (3) emotions; (4) physical functioning; and (5) behavior and adaptive functioning. These five areas encompass the processes by which humans know about themselves and the world around them; how they think, reason, learn, and express themselves; how they feel and express these feelings; how they perceive their bodies, experience their sensations, and perform essential functions; and how they act and react to both internal and external stimuli.

Each of these major domains of psychopathology is the subject of one of the chapters in this section. In addition, Chapter 30 discusses techniques and tests to elicit the manifestations of psychiatric illness during a psychiatric evaluation of an adult patient and Chapter 31 discusses the assessment of children and adolescents. Chapter 32 addresses the specialized areas of neuropsychological and neurophysiological testing and Chapter 33 presents guidelines for the use of brain imaging techniques to aid in the differential diagnosis of neuropsychiatric conditions. Finally, Chapter 39 describes the variation in the manifestations of psychiatric illness, depending on the particular ways in which mental distress or disorder is conceived, experienced, and expressed according to a person’s cultural context.

In this chapter, we discuss the ways in which psychiatric illness presents across the life span and in which the manifestations of disorder may vary according to the patient’s developmental life stage (e.g., infancy, childhood, adolescence, adulthood, and late life). We also discuss variation by gender, because psychiatric disturbance often takes different forms in men and in women. Fundamental to our discussion is the notion that different life stages (and genders) are associated with differential incidence and prevalence rates of particular mental disorders as a result of the developmental tasks of the epoch and corresponding stressors (Rutter 1989a). Thus, developmental considerations may help to explain both the origins of individual disorders and their course (Rutter and Taylor 2002). In addition, age appears to have a pathoplastic effect on the manifestations of psychiatric illness such that the same disorder may have different manifestations at different ages.

### Continuity, Persistence, and Progression Across the Life Cycle

Epidemiological research suggests that considerable stability or continuity of mental disorders can be observed from childhood into adolescence, at least for broad diagnostic groupings. In particular, behavior disorders in childhood are associated with increased risk of behavior disorders in adolescence, especially for boys, and childhood emotional disorders are associated with increased risk of adolescent emotional disorders, especially for girls (Costello and Angold 1995). The more severe the disorder, the more likely it is to persist (Cohen et al. 1993a). In addition, epidemiological surveys of adults indicate that the age at onset of disorders for many patients was during adolescence (Burke et al. 1990) and that most adults with mental disorders had received a diagnosis before 15 years of age (Kim-Cohen et al. 2003), further reinforcing the notion of persistence or progression of disorders from childhood across the life span. Continuity
can be either homotypic, that is, when the same disorder is observed over time, or heterotypic, when there is continuity of disorder but a different diagnosis (Costello et al. 2003). Homotypic continuity indicates chronicity of disorder over time, while heterotypic continuity suggests a shared vulnerability to mental disorder of genetic or environmental origin (Krueger et al. 2002). Juvenile-onset forms of disorders tend to be associated with more severe childhood risks and have a worse prognosis in adulthood. Thus, early identification becomes imperative for prevention efforts.

**Stress-Diathesis Model of Psychopathology**

Theories of the causes of mental disorders are many and are the subjects of other chapters. For simplicity, we take the position that etiology in psychopathology is multifactorial. Most mental disorders are likely to be caused by both a predisposition or a vulnerability at the level of brain biochemistry and experience with acute life events or chronic stressful life circumstances. Such a model helps to explain why a person with a strong family history of depression, for example, may be asymptomatic for long periods but may experience depression after a loss. In a population-based survey of female twin pairs, severely stressful events such as the death of a close relative, assault, serious marital problems, and divorce or breakup significantly predicted the onset of major depression in the month of occurrence. For individuals at highest genetic risk for depression, the probability of onset of major depression was significantly higher after stressful events than for individuals at lowest genetic risk, suggesting “genetic control of sensitivity to the depression-inducing effects of stressful life events” (Kendler et al. 1995). Overall sensitivity to stressful life events may be moderated by a functional variant in the serotonin transporter gene (Caspi et al. 2003), which may make individuals more sensitive to mild stressors (Kendler et al. 2005). High levels of lifetime exposure to adversity have also been causally implicated in the onset of depressive and anxiety disorders (Turner and Lloyd 2004). Some disorders, however, may be exclusively caused by disease processes that directly alter brain structure and function or by exogenous or environmental factors such as drugs or toxins. A few disorders may be the result solely of psychosocial stressors.

**Resilience**

In addition to understanding the development and progression of psychopathology in terms of vulnerabilities and risks, recent interest has turned to consideration of protective factors and resilience as mediators of the course of mental disorders (Rutter 1985). Psychobiological, personality, and social behavioral factors have been identified that together may serve to protect a person from stress (Charny 2004). Resilience refers to individual differences or life experiences that help people to cope with adversity, make them better able to deal with stress in the future, and confer protection from the development of mental disorders. A number of neurotransmitters, neuropeptides, and hormones have been linked to the psychobiological response to stress and to long-term psychiatric outcomes, including cortisol, corticotropin-releasing hormone, neuropeptide Y, galanin, dopamine, serotonin, testosterone, and estrogen. Adaptive individual traits include intelligence, optimism, self-confidence or efficacy, sociability, internal locus of control, and active style of coping. Protective life experiences are often the product of strong “social support,” both within the family and in the outside community. Perceived social support from a caregiver has been shown to be protective against the development of depression in maltreated children, even if they were genetically vulnerable (Kaufman et al. 2004). Integration of biological, psychological, and social processes hold promise for a fuller understanding of both normal and abnormal development and especially of the critical role of resilience in development (Masten 2001, Rutter 2002a).

**Pathplastic Effects of Age**

Age appears to influence psychopathology in three ways (Table 29–1). A few mental disorders appear almost to be age specific and not to occur outside a certain age range. Feeding disorder of infancy or early childhood (failure to thrive) is a disturbance restricted to the first several years of life because of a child’s total dependence on caregivers for food during this time. Dementia of the Alzheimer’s type is much more common after the age of 65 years; few cases develop before the age of 50 years.

</table>

More commonly, disorders that may occur at virtually any age have a usual onset at certain stages in life. Mental retardation, learning disorders, disruptive behavior disorders, and elimination disorders, among others, usually have their onset and are first diagnosed during childhood. The median age at onset for the first psychotic episode of schizophrenia is in the early-to-mid 20s for men and in the late 20s for women (American Psychiatric Association 2000).

Most mental disorders can occur at various times in life’s stages. Some of these are expressed differently depending on age. For example, although the core symptoms of major depression are the same regardless of a person’s age, in children somatic symptoms, irritable mood, and social withdrawal may be especially common. In depressed elderly persons, cognitive symptoms such as memory loss, disorientation, and distractibility may predominate.

**Problems of Childhood**

**Individual Differences**

Children differ from each other in ways that affect their psychological functioning from birth. They differ in intelligence, temperament, and in genetic endowment for both risk for and resilience against mental disorder.

Intelligence is the ability to reason, plan, think abstractly, solve problems, understand, and learn. Average intelligence is associated with a score of 100 (IQ) on a standardized intelligence test. About 67% of children have IQs between 85 and 115 and about 95% between 70 and 130. Estimates of the heritability of IQ range from 0.4 to 0.8 (Plomin 1990) and indicate that heredity plays a larger role than environment. Higher intelligence is correlated with successful adaptation in life, and substantially reduced
intelligence is associated with developmental and behavioral problems and functional impairment (see the discussion of mental retardation).

Children also differ at birth in certain fundamental behavioral predispositions, such as emotionality, activity, and sociability, called temperament (Buss and Plomin 1975). Thus, some children are born with a calm and placid nature; others are inclined to be active and energetic. Thomas et al. (1968) found that some children showed particular clusters of temperamental characteristics. “Difficult” children had irregular sleeping and eating patterns, tended to withdraw from new situations, were not adaptable, and had intense and negative reactions to stimulation. “Easy” children were biologically regular, adaptive, and in good moods; they had positive reactions to new situations and reactions to stimuli that were mild in intensity. “Slow-to-warm-up” children had initial withdrawal responses, slow adaptation, and mild reactions. Some aspects of temperament have been shown to be remarkably stable throughout childhood and adolescence and into adult life (Kagan et al. 1988, Chess and Thomas 1977). A shy, inhibited temperament may predispose to the development of childhood anxiety disorders and to inhibited, avoidant personalities in adult life (Biederman et al. 1990). A difficult temperament has been thought to be a predisposition for behavior disorders (Thomas and Chess 1984).

More recent work suggests that temperament may be a unifying basis for understanding personality/psychopathology relationships (Clark 2005). Three broad temperament dimensions—negative affectivity (emotionality, neuroticism, and harm avoidance), positive affectivity (approach and extraversion), and disinhibition (novelty seeking vs. constraint, effortful control)—differentiate through developmental processes into personality traits and, at their extremes, are risk factors (diatheses) for psychopathology, especially under adverse life experiences. For childhood disorders, one proposal suggests that conduct disorder arises from low fear response and high incentive approach, attention deficit hyperactivity disorder from low effortful control and strong approach, and anxiety disorders from high negative emotionality and low effortful control (Nigg 2006). The concept of goodness of fit between an individual’s capacities and behavioral style and the expectations and demands of others in the environment may be important in determining outcome. In one of the few studies to test the goodness of fit hypothesis, childhood novelty seeking in combination with high maternal novelty seeking was associated with child attention problems, whereas the combination of high child harm avoidance and high paternal harm avoidance was associated with child internalizing problems (Rettew et al. 2006).

Inheritance has been shown to play a role in the development of certain developmental disabilities, enuresis, schizophrenia, and mood and anxiety disorders. As mentioned earlier, heredity does not indicate with certainty that an individual will develop a mental disorder. Instead, a susceptibility is inherited, and some life experiences or other environmental factors are often required for a disorder to become manifest. Factors that lead to greater resilience in the face of adversity (Rutter 1985) and consequently lessen the risk of mental disorder, such as intelligence, adaptability, and sociability, also have genetic components.

### Types of Problems

Psychopathology in childhood falls into five major groups of problems (Table 29–2). Many of the disorders of childhood appear to be severe forms of problems that are more or less continuously distributed, common, and “normal” occurrences. Thus, clinical depression may appear to be a severe form of sadness and disappointment, conduct disorder a severe form of aggressiveness, and anorexia nervosa a severe form of adolescent dieting and dissatisfaction with body shape (Rutter and Sandberg 1985). However, although dieting and concerns about body shape may be relatively common among young women, anorexia nervosa is actually quite rare, suggesting a discontinuity between normal problems and psychopathology. Therefore, identification of a clinically significant disorder involves consideration of both the quantitative severity of a disturbance and its persistence and qualitative distinctions, such as the impact of the problems on the child’s functioning, continued development, and adaptation to life (Rutter 1989b). Differences between cases and noncases may depend on fundamental differences in biology, personality, or social environment.

A recent review of epidemiological studies of childhood and adolescent psychiatric disorders yielded a median prevalence of 12% for problems considered functionally impairing, although prevalence rates among studies varied widely (Costello et al. 2005). For example, one study showed that while the 3-month prevalence rate of any disorder was 13.3% in a group of children aged 9–13 years, the risk of having at least one psychiatric disorder by the age of 16 years was much higher (Costello et al. 2003). Another international epidemiological review estimated a prevalence of psychopathology ranging from 10% to 20% in young people (Fombonne 2002). Overall rates of mental disorders and rates of individual disorders are lower when impairment criteria are more stringent and higher when they are relaxed. Rates are lowest when the need for treatment is included in the criteria for disorder. Rates vary by the age range of the population studied, whether the children are evaluated in clinical settings or in the community, and the period of time over which the disorder can be present (Cohen et al. 1996). Rates are also influenced by who provides information and how many sources of information are used. In general, children are usually more aware of their emotional problems than are their parents, but parents report more behavioral problems (understandably) than do their children. The more people who provide information on symptoms, the more diagnoses are made. More boys than girls are affected until the age of 11 years; more girls than boys are affected from the age of 12 years and older. The co-occurrence of several disorders (i.e., comorbidity) is common in childhood, which raises questions about the diagnostic systems being employed and also the relationships of various disorders with one another (Caron and Rutter 1991, Taylor
Thus, children with learning disorders are likely to have more than one disorder and are likely to have communication and behavior disorders as well. Children with behavior disorders may also have more than one and are likely to have learning and communication disorders. Mood and anxiety disorders co-occur and are found additionally in children with learning and behavior disorders.

Recently, interest has increased in identifying emotional and behavioral disorders in preschool children. Despite the relative lack of research on preschool psychopathology, using developmentally appropriate diagnostic criteria indicates that rates of common disorders and patterns of comorbidity are similar to those seen in later childhood (Egger and Angold 2006). At risk children from high SES families may be identified as early as infancy (family histories of psychopathology and greater family stress during infancy), whereas those from low SES families may be identified as preschoolers (Essex et al. 2006). In a birth cohort followed for 3 years, the number of behavioral and emotional problems observed in the young children increased with the number of mental health problems (depressive episode, substance abuse, and domestic violence) experienced by the mother in the first year after birth (Whitaker et al. 2006).

### Developmental Problems

Childhood is a time of growth, physical and social maturation, and the acquisition of skills necessary to deal independently and successfully with the environment. Children who are greatly delayed in their development or who never acquire the requisite skills or maturity associated with their developmental stage have developmental problems. Developmental disorders fall into five main types: intellectual, learning, motor skills, communication, and pervasive developmental disorders.

Significantly subaverage intelligence recognized before the age of 18 years and accompanied by impairment in adaptive functioning is called mental retardation. Approximately 1% of the population is estimated to be mentally retarded. Boys are slightly more likely to be diagnosed with mental retardation than are girls (American Psychiatric Association 2000).

Intelligence is defined by the IQ, which is measured by a standardized, individually administered test, such as the Wechsler Intelligence Scale for Children (Revised) or the Stanford-Binet Intelligence Scale. Subaverage intelligence is indicated by a score of approximately 70 or below on one of these tests, corresponding to approximately two standard deviations below mean intelligence scores. Mental retardation is commonly specified by degree of severity as mild, moderate, severe, or profound (Table 29–4). Impairment in mental retardation is the inability to meet functional standards for the person’s age and sociocultural group and is exhibited by deficits in communication skills, self-care, home living, interpersonal relations, self-direction, academic skills, work, leisure, health, or safety.

The causes of mental retardation can be grouped from most to least common as follows (American Psychiatric Association 2000):

1. Alterations in embryonic development, such as those caused by chromosomal abnormalities or fetal exposure to drugs or toxins.
With advances in genetic technologies, the field has shifted so that impairment in adaptive functioning is no longer considered to have a clear biological etiology, while the other group had no evident organic basis for the disability. Mental retardation may be recognized at birth if it is apparent.

Mental retardation may be recognized at birth if it is due to a condition like Down’s syndrome with physical manifestations. Likewise, it can be noted readily after a severe medical illness affecting the CNS. Severe retardation is commonly associated with lifelong functional impairment and shortened life expectancy. Milder forms of mental retardation may be responsive to appropriate training and support and so that impairment in adaptive functioning is no longer apparent.

Children with mental retardation often have other problems besides their intellectual deficits and may be diagnosed with behavioral, emotional, or other developmental disorders as well.

When a child’s performance on standardized achievement tests falls substantially below what would be expected given her or his IQ, age, and schooling, the child is said to have a learning disorder. Learning disorders may involve primarily subaverage reading, mathematical, or writing ability. Rates of significant underachievement in reading range from 3 to 9% of school children, depending on measurement methods employed, with boys outnumbering girls by 3 or 4 to 1 (Snowling 2002). Learning deficits adversely affect the child’s academic functioning or other activities of daily living that require proficiency with these skills. Vision or hearing impairment may also interfere with academic achievement. Learning disorders are diagnosed in children with limited sight or hearing only when the deficits are even greater than would be expected given the sensory problem. Children with learning disorders also often have other behavioral and emotional problems (Jorm et al. 1986, Rourke and Fuerst 1991).

Specific learning disorders are usually diagnosed when formal training in reading, mathematics, or writing begins in school. If the child is significantly above average in intelligence, the learning deficits may not be recognized until after several years of school. Most untreated learning disorders persist into adult life, with consequent emotional and behavioral problems and varying degrees of functional impairment, depending on environmental opportunities and demands (Snowling 2002).

Motor skills disorder involves marked impairment in motor coordination. Incoordination is of such a degree of severity that it limits the child’s ability to locomote or to perform tasks in school (such as handwriting) or otherwise interferes with activities of daily living, such as getting dressed. Developmental coordination disorder has been estimated to affect as many as 6% of children between the ages of 5 and 11 years (American Psychiatric Association 2000). Traditionally, boys have been observed to have the disorder more frequently than girls, but recent studies have shown similar rates across genders. The discrepancy has been explained either as a result of a tendency for boys to be referred for testing or services more readily than girls or greater social pressures for boys to excel in sports than girls (Spagina et al. 2000). The problems of coordination indicative of a motor skills disorder are to be distinguished from those associated with neurological disorders such as cerebral palsy. Motor skills problems also tend to persist, at least into the teens, with self-esteem and school problems typical of other learning disorders (Loose et al. 1991).

Communication disorders subsume problems in self-expression using language, in understanding language, in articulating appropriate speech sounds, and in speech fluency and timing. Communication problems may be acquired as a result of CNS infection, toxin exposure, or trauma or may be developmental, that is, not associated with neurological insults of known origin. Children may not develop an age-appropriate amount of speech, range of vocabulary, complexity of speech, or appropriate grammatical construction. If these problems significantly interfere with academic achievement or social development, an expressive language disorder is diagnosed. If a child is also unable to understand words and sentences, a receptive-expressive language disorder is present. If a child has a significant problem in pronouncing or articulating sounds required for speech, the impairment is referred to as phonological disorder. If a child has a problem in the fluency or patterning of speech, such that there are sound, syllable, or word repetitions plus frequent pauses, broken words, and sound prolongations, the problem is called stuttering.

The developmental types of expressive or mixed language disorders affect approximately 3–5% of children; the acquired types are more rare (American Psychiatric Association 2000). Phonological disorder occurs in 2–3% of children and stuttering in about 1%. The sex ratio for language disorders and stuttering has been estimated to be as high as three boys to one girl. Differences in rates are attributed to differences in study sampling practices, testing procedures, and diagnostic criteria (Johnson and Beitchman 2000).

Communication disorders become evident as language becomes more complex. Severe problems with expressive or receptive language of a developmental type (i.e., not acquired through CNS disease) are evident in the first 2 or 3 years of life. More subtle disturbances may not become apparent until the demands of formal schooling occur. Articulation and stuttering problems are also usually apparent before the child begins school. In many instances, communication disorders are time limited or reversible. The prognosis for acquired types of language disturbance may be poorer than for the developmental type and depends on the nature and severity of CNS damage.

Sometimes children have many different problems in development, involving communication, social skills, and behavior. When these problems are extremely deviant for the child's developmental stage, they are diagnosed as pervasive developmental disorders (Rutter and Schopler 1992). The subtypes of the pervasive developmental disorders are discussed in Chapter 45. The prototype disturbance is called autistic disorder. Children with autistic disorder fail to develop the abilities to interact socially and to communicate effectively, and frequently have restricted and stereotyped behavior patterns and interests. They are socially isolated, uninterested in peer activity or sharing, and apparently unable to have reciprocal interactions either nonverbally or emotionally with others (Lord and Rutter 1994). They also either do not speak or speak in limited or idiosyncratic ways. A typical repetitive, stereotyped behavior is hand or finger flapping. Boys are four to five times more likely than girls to have autism. Moderate mental retardation is a common additional problem. Autistic disorder has traditionally been considered to be rare: DSM-IV-TR states that it affects only about five children in 10,000 (American Psychiatric Association 2000). Recently, however, the rate of reported pervasive developmental disorders has increased, with greater awareness of these problems and attention to diagnosis and the identification of a "spectrum" of autistic disorders. A recent epidemiological survey found a prevalence of almost 60 per 10,000 for all pervasive developmental disorders and 22 per 10,000 for autistic disorder itself (Chakrabarti and Fombonne 2005). The disorders continue to be found much more commonly (85.9%) in boys. The social deficits characteristic of autism spectrum disorders can be found fairly readily in the general population, are continuously distributed, and moderately to highly heritable (Constantino and Todd 2003).

A variety of perinatal factors have been associated with autism, including advanced paternal, especially paternal age, being the first-born child, mother having threatened abortion and induced labor, fetal distress, delivery by Caesarian section, and Apgar score less than 6 at 1 minute (Glassen et al. 2004, Reichenberg et al. 2006). More of these factors have been found for cases of autism than for PDD NOS (pervasive developmental disorder not otherwise specified) or Asperger's syndrome. They reflect underlying genetic problems or the interactions of such factors with the environment.

The most severe developmental problems are evident in infancy. The infant with autism may manifest limited eye contact, facial responsiveness, and smiling and may be difficult to hug or may appear to dislike physical contact. Restricted social relationships emerge, however, after the third or fourth year of life. For children with other pervasive developmental disorders, infancy may be normal, with the onset of the abnormal behaviors occurring months or even years after birth. In milder forms, such as Asperger's syndrome (Tantum 1988), in which communication skills are spared, a pervasive developmental disorder may not be recognized until preschool or the actual beginning of school. The course after diagnosis is variable, depending on the subtype. In some cases, there is limited improvement; in other cases, there is progressive deterioration. Autism diagnosed at the age of 2 years had high diagnostic stability at the age of 9 years in a recent follow-up study (Lord et al. 2006). Pervasive developmental disorders cause lifelong impairment: persons with intellectual impairment need supervised living and working situations; those with normal intelligence and higher levels of language acquisition may achieve a degree of independence by their 30s (Lord and Bailey 2002). Outcome studies indicate that approximately two-thirds of children with autism are unable to lead an independent existence, and one-third make some social and educational gains. Patients with a history of autism may be diagnosed with personality disorders as adults (Anckarsater et al. 2006). About one-tenth of all individuals with autism may have a good outcome with some social life and adequate functioning at work or at school (Volkmar and Klin 2000).

### Emotional Problems

The emotional problems of children involve anxiety, depression, and mania. Although these problems have counterparts in adults, children frequently experience and express their disturbances of feelings or emotions differently from adults. Because of their more limited vocabulary and understanding of emotional life, children may not express their emotional distress verbally as well as some adults do. Thus, even in the emotional disorders of childhood, disturbances in behavior and in physical functioning are apt to be prominent in the clinical presentation. Children are not unlike so-called alexithymic adults, whose expression of emotions is indirect and nonverbal.

Because some childhood anxieties are common and have an adaptive function, and the severity of anxiety at various stages of childhood and adolescence appears to be on a continuum, it is often unclear where normal fears shade into pathological states (Klein and Pine 2002). Thus, animal phobias appear in early childhood, when normal children may also have milder fears of animals; pathological and normal performance anxieties occur in late childhood; and social anxiety, both mild and severe, has its usual onset in adolescence (Öst 1987). An exception is pathological separation anxiety, which has a peak age at onset in community and clinical samples in late childhood (Bird et al. 1988, Last et al. 1992), although normal, developmentally appropriate separation anxiety occurs during the first year of life. Rates of anxiety disorders tend to decline with increasing age in childhood and adolescence (Cohen et al. 1996).

A child with separation anxiety fears separation from home or from attachment figures such as parents. A common first expression occurs when the child is faced with going to school (or preschool) for the first time. The young child may refuse to go to school, may exhibit clinging behavior, or may complain of physical symptoms such as headache or stomachache. Other, early, non-school-related manifestations of separation anxiety include insistence on
sleeping with parents, nightmares, and fears of the dark. Separation anxiety may be precipitated by a stressful event, such as a family death or illness or a move or change of schools. Older children express the fear that calamity will happen either to themselves or to the person(s) to whom they are attached. The course of separation anxiety may wax and wane, but whenever a developmentally appropriate separation is imminent, such as going away to college, a susceptible person is anxious in anticipation of it and may actually avoid the separation or come home prematurely. Separation anxiety disorder is more common among girls. About 4% of children may have the disorder (American Psychiatric Association 2000). Children with separation anxiety disorder may also have mood disorders. Adult separation anxiety disorder may be more common than previously suspected (over 6% prevalence) (Shear et al. 2006). About one-third have an onset in childhood that persists, but the rest have an adult onset.

Selective mutism is an emotional condition in which a child has ceased speaking in certain situations (e.g., at school), although the child has normal or near-normal speech and does, in fact, speak in other situations (e.g., with friends or parents) (Tancer 1992). It has been suggested that this syndrome is more properly regarded as an anxiety disorder, rather than a speech and language disorder, although some children with selective mutism do have language problems that may make them self-conscious about speaking. Girls are two to three times more likely to manifest selective mutism than boys, and evidence has shown that it is more likely to be related to temperament rather than abuse or trauma (Bishop 2002). Reluctance to speak when first entering school occurs in about 1% of children (Brown and Lloyd 1975) and usually remits spontaneously.

Fears of social or performance situations in which a child is exposed to the scrutiny of others and is afraid of being humiliated or embarrassed is called social phobia. Shy or fearful temperament is a predisposing factor. Social phobia may be manifest by the young child by crying, tantrums, clinging to familiar figures (parents), or mutism. The slightly older child may not wish to play with peers or may refuse to go to school. Social phobia may be more limited (i.e., restricted to a performance situation such as speaking in class) or more generalized (i.e., involving a fear of most social situations). The prevalence of social phobia in children is about 1% (Anderson et al. 1987, Costello et al. 1988). The course of social phobia is often characterized by exacerbations caused by life stressors and social demands followed by remissions when situations pass or stabilize.

Some children may be excessive worriers in general. They may worry about school performance, athletic prowess, appearance and popularity, parental expectations, potential catastrophic events, and so on. Children who worry excessively are said to have generalized anxiety disorder. About 3-4% of preadolescent children may be affected (Anderson et al. 1987, Costello et al. 1988). They may also be excessively conforming and perfectionistic and insecure to the point of extreme self-consciousness and needs for reassurance. Generalized anxiety is also likely to have a fluctuating course, with more symptoms during times of stress.

Children may develop compulsive behavioral rituals involving counting, checking, washing, or ordering. Boys are more likely to be affected than girls, especially before the age of 7 years (Swedo et al. 1989a). Preoccupation with rituals and obsessional thoughts may lead to impaired school performance. Parents are likely to bring compulsive behaviors to clinical attention as they do in the case of the behavior disorders. Children are less likely than are adults to recognize their behaviors as excessive and unreasonable.

Traumatic events in childhood are common. Two-thirds of children may experience at least one traumatic event by the age of 16 years (Copeland et al. 2007). Children may develop post-traumatic stress symptoms or disorder (PTSD) or other anxiety or depressive disorders after a severely traumatic event (Hoven et al. 2005, Meiser-Stedman et al. 2005, Roussos et al. 2005). Girls may be more vulnerable than boys. In children, distressing dreams are usually nightmares; reliving experiences are often reenactments of the traumatic event in play. Separation difficulties may occur. Memory problems, avoidance of situations reminiscent of the trauma, and hyperarousal symptoms are also reported (Yule 2002). Diminished interest and responsiveness may be evident only to others, as children tend not to report such complaints on their own. Children with PTSD sometimes feel they will never live to be adults or become preoccupied with “telling” the future. Somatic complaints such as headaches and stomachaches are common. Childhood risk factors for developing PTSD include experiencing multiple traumas, externalizing behavior problems (increasing exposure to traumatic events), mood and anxiety problems (increasing reactivity), and family and environmental adversity (Koenen et al. 2007, Storr et al. 2007). Higher intelligence among young children has been found to decrease both risk of exposure to trauma and of PTSD development throughout childhood and adolescence (Breslau et al. 2006).

Moody periods are common in children, but children may also exhibit prolonged and persistent disturbances of mood, usually depression. Although study estimates vary by assessment method, one estimate of the prevalence of major depression among young children is between 0.5% and 2.5% (Harrington 1994). Again, feelings of depression may not be experienced by children in the same way as by adults or may not be readily articulated (Rutter 1986). Children who are depressed may be more likely to complain of boredom or of being unable to have fun. They may become socially withdrawn and tend to want to stay at home rather than attend school (Harrington 1994). Depressed children cry and express self-criticism and thoughts about death. Energy level is significantly diminished, and depressed children tend to sleep significantly more than usual. Eating habits may change. Irritability and somatic complaints may be prominent symptoms. In prepubertal children, depressive episodes tend to occur in association with behavior or anxiety disorders (Angold and Costello 1993). Although prepubertal depression has been shown to be strongly familial (Harrington et al. 1993), depressive episodes are frequently triggered by some type of loss, such as the death of a parent, a divorce, a serious illness, or a move to a new town or neighborhood, often in the context of chronic adversity (Goodyer et al. 1988). Although some studies report the childhood sex ratio for depressive disorders at about 1:1 (Fleming et al. 1989, Velez et al. 1989), there is also evidence of greater prevalence in boys (Angold et al. 1998). By adolescence, more girls than boys are affected (Angold et al. 1998, McGee et al. 1990).
Continuity of Antisocial Behavior Across the Life Span

Although the vast majority of preadolescent children with depressive episodes recover within 2 years (Kovacs et al. 1984a), up to 70% are likely to have another episode within 5 years (Kovacs et al. 1984b). Children who also have chronic mild depression have a poorer short-term outcome (Asarnow et al. 1988). Patients whose symptom picture most resembles that of severe adult-like presentations and who do not have comorbid conduct disorder are more likely to have continuity of depressive illness into adult life. Older depressed children may have a worse prognosis than younger ones (Kovacs et al. 1989, Harrington et al. 1990). Childhood major depressive disorder also appears to increase the risk for the development of personality disorders in young adulthood (Kasen et al. 2001).

Mood and anxiety disorders commonly occur together in childhood. In roughly one-third of cases anxiety begins first, in one-third depression begins first, and in one-third the onset is simultaneous ( Moffitt et al. 2007). Mood disorders in adolescence and young adulthood may be best predicted by internalizing problems in childhood and anxiety disorders by social problems and externalizing behaviors (Roza et al. 2003).

The manifestations of mania in younger children may involve irritability, emotional lability, hyperarousal, or admixtures of dysphoria and hypomania, as well more typical symptoms of hyperactivity, grandiosity, pressure of speech, and distractibility (Carlson 1990, Strober et al. 1989, Leibenluft et al. 2003). Children themselves are more likely to report classic symptoms than their parents, who focus more on problematic behavior (Tillman et al. 2004). Episodes of mania in children may last only a couple of days, but long episodes and chronic, unremitting patterns of mania and mixed mood disturbances have also been observed (Axelson et al. 2006, Geller et al. 2004, Birmaher et al. 2006), suggesting a spectrum of bipolar illness in children. One-third to one-half of children with major depressive episodes may show bipolar disorder by adolescence (Geller et al. 1994, Chengappa et al. 2003). Early-onset bipolar disorders may have a poorer prognosis than later onset disorders (Geller et al. 2004). Children with severe mood dysregulation also are diagnosed with attention-deficit/hyperactivity disorder (ADHD), conduct disorder, and oppositional-defiant disorder (Brotman et al. 2006).

Behavior Problems

Behavior problems in children fall into the general groupings of oppositional behavior, hyperactivity, excessive aggressiveness, and conduct disturbance. An appropriate degree of control over behavior is a necessary development for a child to function in a family, in school, and with peers.

A certain amount of oppositional behavior toward parents is a normal phenomenon in the preschool years (e.g., the ‘‘terrible twos’’). When oppositional behavior is excessive, given a child’s developmental stage, and adversely affects social or academic functioning, it is pathological (Keenan and Wakschlag 2004). Oppositional children are negative, hostile, and defiant. They frequently lose their temper; are argumentative with adults; defy rules and expectations set by adults; are easily annoyed and deliberately annoy others; and are angry, resentful, spiteful, and vindictive. In the preschool years, oppositional children are often those who have difficult temperaments (e.g., high reactivity, difficulty being soothed) and who are hyperactive. When the problem is not associated with hyperactivity, it is often the result of a family in which parents have not been able to set appropriate standards for behavioral compliance in their children or to set limits with appropriate punishments when expectations for behavior are deliberately opposed. Oppositional behavior is sometimes a forerunner of conduct disorder (Schachar and Wachsmuth 1990, Loeb et al. 1991) (Table 29–5). Oppositional behavior causing significant social or academic impairment is diagnosed as oppositional defiant disorder. The disorder is common among children in the community with a psychiatric condition and may affect nearly 6% of children overall (Rey 1993). Oppositional defiant disorder is twice as common in boys as in girls 12 years of age or younger. Oppositional defiant disorder has been shown to be a strong disk factor for the later development of conduct disorder in boys but not girls (Rowe et al. 2002). In adolescence, more girls may have the disorder, along with depression and anxiety.

Hyperactivity is also common in young children. Hyperactivity is not a problem unless it is severe enough to preclude a child’s focusing attention on learning or play activities. The hyperactive child is constantly fidgeting and squirming, moves about constantly as if driven by a motor, and shows signs of impulsivity. Much of the motor activity is not goal directed and has a disorganized, chaotic quality. Thus, qualitative differences in activity as well as quantitative differences are significant (Schachar and Tannock 2002). Hyperactive children do not play well and demand constant attention and supervision. The inattentive child is easily distracted and forgetful, seems unable to organize activities, cannot follow instructions, and does not appear to listen.

Sometimes hyperactivity is evident from the age of 3 years, but more often it is diagnosed after the child begins school, when the behaviors may become disruptive and interfere with forming peer relations and with learning. Hyperactivity with attention deficits occurs two to nine times more commonly in boys than girls (predominantly inattentive types have a less pronounced gender ratio) and affects about 3–5% of children (American Psychiatric Association 2000). Gender differences in ADHD clinical correlates are not evident in children who have not been referred for clinical attention (Biederman et al. 2005). Most children diagnosed with ADHD around the age of school entry
continue to demonstrate symptoms and impairment well into elementary school (Lahey et al. 2004), although the types of symptoms expressed over time may change (Lahey et al. 2005). Both boys and girls with a diagnosis of ADHD are at increased risk for developing other comorbid behavioral, addictive, mood, and anxiety disorders by young adulthood (Biederman et al. 2006a, 2006b).

Mannuzza and Klein (2000) have estimated that two-thirds to three-quarters of children with ADHD will experience symptoms into adolescence, with relative social and academic deficits, and at times, conduct disorder behaviors. One-quarter to one-third will meet criteria for antisocial disorder in later adolescence and a significant minority will become involved with drug abuse; ongoing ADHD symptoms seem to be implicated. However, while some difficulties may persist into adulthood, a majority go on to function adequately in social and occupational areas and two-thirds who originally received a diagnosis of ADHD show no mental disorder as adults (Mannuzza et al. 1998). A small percentage (about 10%) of patients (Mannuzza et al. 1993) have continuing subtle problems into adult life, which lead them to be emotionally labile with problems controlling moods and temper, and to be disorganized and distractible with problems in sustaining effort and completing tasks (Wender et al. 1985). By the age of 25 years, only 4% of boys continue to have ADHD (Mannuzza et al. 1998). Inattention symptoms decline at a slower rate than hyperactivity or impulsivity symptoms (Biederman et al. 2000).

Assertiveness, aggressiveness, and expression of anger are also on a continuum of severity and adaptiveness in children. Children can be excessively passive, or they can have a problem with too much aggression if they repeatedly and consistently hit, bite, or kick others; destroy property (including toys); or injure animals. When excessive aggression toward other people or animals, destruction of property, deceitfulness or theft, or other serious violations of parental or school rules are repetitive and persistent, a conduct disturbance exists. Conduct disturbance beginning in childhood tends to be much more common in boys than girls (Offord et al. 1987). Boys and girls also differ in their antisocial behaviors. Boys tend to have fighting, stealing, and school discipline problems; girls exhibit lying, truancy, running away, substance abuse, and prostitution.

The causes of conduct disturbance are multiple and can include interrelated genetic, biological, and environmental factors. For example, child abuse has been identified as a causal risk factor, and in turn, child abuse affects cognitive, emotional, and neuroendocrinological processes. As well, there seems to be causal relationship between familial presence of conduct and antisocial behavior, but it has been very difficult, even in twin studies to tease out the genetic and environmental aspects of etiology (Earls and Mezzacappa 2002). Excessive aggressiveness and conduct problems have been shown to be heritable (Scourfield et al. 2004), while environmental factors such as parental neglect, poor quality of parenting, parent-child conflict, and malnutrition also exert strong influences on a variety of childhood externalizing problems (Kolvin et al. 1988, Burt et al. 2003, Liu et al. 2004). Growing up in a family in which violence and abuse are modeled by parents may also promote aggressive patterns of dealing with problems by children. Physical abuse of children themselves tends to provoke a panoply of negative, impulsive, angry, and aggressive behaviors. Television and the movies provide reinforcement for the aggression-prone child’s behavior. Lack of consequences for inappropriate aggressiveness, excessive physical punishment, and inconsistency of parental response to hurtful or destructive acts of children all tend to exacerbate conduct problems.

Conduct disorder is sometimes seen as early as 4 to 5 years of age (Kim-Cohen et al. 2005). It is most frequently diagnosed in later childhood or early adolescence, however, and is rare in onset after the age of 16 years. Early onset, hyperactivity or inattention, poor peer relationships, and family discord and disorganization predict a worse prognosis, with a significant number of children developing anti-social personality as adults (Robins 1991, Zoccolillo et al. 1992). Conduct disorder with an onset in childhood and a persistent course has been shown to be associated with greater physical and mental health burden at the age of 32 years than adolescent-onset conduct or conduct disorder limited to childhood (Odgers et al. 2007). Children with conduct disorder also often have problems with mood and anxiety disturbances and substance abuse. A developmental progression from ADHD to conduct disorder to alcohol or tobacco use to abuse of marijuana and other street drugs has been observed (Kupernik et al. 2001). Childhood disruptive behavior disorders as a group have also been shown to predict the development of personality disorders in young adulthood, with an increased effect when multiple, comorbid childhood disorders are present (Kasen et al. 1999). One notable study that followed over 1000 children from the age of 3 to 26 years, showed that a significant number of those who met criteria at the age of 26 years for a wide variety of mental disorders (i.e., affective and anxiety disorders, not only antisocial personality disorder), had been diagnosed with conduct and/or oppositional defiant disorder in childhood (Kim-Cohen et al. 2003).

Disturbances in Physical Functioning
A number of developmental tasks of childhood involve primarily physical functions. These include developing proper eating and sleeping habits (Stein and Barnes 2002), and bowel and bladder (Clayden et al. 2002) control. Disturbances may occur in these functions during childhood.

The eating disturbances of early childhood are rumination, failure to thrive (feeding disorder), and pica (Minde and Minde 1986). Rumination involves regurgitation and rechewing of food, without any structural anomaly or physiological disturbance to account for it. The problem is rare and is diagnosed most often in the first year of life. This early-onset syndrome occurs in developmentally normal children in association with a disturbed caretaker-child relationship (Mayes et al. 1988). Rumination may also be associated with mental retardation and may occur somewhat later in these children. It usually remits spontaneously.

Failure to thrive is a syndrome that also most commonly begins during the first year of life and consists of a child not eating enough to grow or in fact losing weight. Again, the feeding disturbance occurs in the absence of a medical condition, such as a disorder of intestinal absorption, which could cause weight loss. The behavior may remit after hospitalization, but long-term problems including mental retardation, developmental delays, and behavior problems are common (Oates et al. 1985).
Pica is a syndrome of eating non-nutritional substances, such as paint, plastic, string, or hair (Bicknell 1975). Older children eat animal droppings, sand, insects, leaves, or pebbles. Pica usually begins in infancy or the first years of life. It may be associated with mental retardation, or it may develop as a result of child neglect. It usually remits spontaneously, although it may occasionally persist into adolescence and rarely into adulthood. Pica in early childhood has been shown to be associated with bulimic symptoms in adolescence (Marchi and Cohen 1990).

Developing a regular sleep pattern is also a task of early childhood. Abnormal behavioral or physiological events occurring in association with sleep are called parasomnias (Mahowald and Ettinger 1990). The common parasomnias are nightmares, sleep terrors, and sleepwalking (Anders 1982). Nightmares are extremely frightening dreams that rapidly awaken children and leave them frightened and unable to go back to sleep. Sleep terrors involve awakening in a panic without recall of a dream and being confused, disoriented, and somewhat unresponsive to others (Thorpy 1990). Sleepwalking involves rising from bed and walking about, unresponsive to others. Disturbed sleep may also be the result of an emotional disorder (such as the nightmares of PTSD) or a general medical condition, such as epilepsy. Nightmares are common in children before the age of 5 years; more girls than boys may have them. Sleep terrors are much rarer and occur most often in school-age boys. Sleepwalking is more common (1–5%) (American Psychiatric Association 2000) in school-age and prepubescent children. Most often parasomnias resolve on their own during adolescence.

When toilet training becomes significantly delayed, a child may have an elimination problem. A 4-year-old child (or a child with a mental age of at least 4 years) who repeatedly passes feces into clothing or onto the floor has enuresis. Encopresis may occur in children who have never had bowel control or whose previously established bowel control is interrupted by psychosocial stress (Clayden et al. 2002). Constipation caused by physical disease or anxiety with resulting overflow incontinence is the most common mechanism. Encopresis is familial, is strongly related to the sphincter abnormality of enuresis, and may be preceded by an early history of sluggish bowel movements. Therefore, constitutional determinants of bowel motility are likely to be important in many cases. Usually, the incontinence is involuntary; occasionally, it may be deliberate and suggest an oppositional pattern of behavior. The latter children are often generally aggressive and from socially disadvantaged families. Encopresis is more common in boys than in girls. Encopresis can be a persistent problem with exacerbations and remissions, but it usually resolves by late childhood.

A child who repeatedly voids urine into clothing or bedding after the age of 5 years has enuresis. Enuresis can also be primary (i.e., the child has never been continent) or secondary. Data from the US National Interview Survey showed that at the age of 5 years, 36% of boys and 30% of girls had wet the bed at least once in the prior year; 16% of both genders wet infrequently; and 5% of boys and 1% of girls wet the bed nightly (Byrd et al. 1996). Bedwetting declined with age, with all but about 1% of cases having remitted by the age of 17 years. Enuresis has been shown to occur in families and to be associated with biological dysfunctions in circadian rhythms and bladder function, as well as other developmental delays (Clayden et al. 2002). Inadequate or inconsistent toilet training and psychosocial stressors, such as entering school or the birth of a sibling, may also predispose to elimination problems. Elimination disorders frequently co-occur with disruptive behavior disorders.

Disorders of movement may also afflict children. Tics are sudden, rapid, recurrent, nonrhythmic stereotyped motor movements or vocalizations that are not caused by medications or other drugs or by general medical conditions. Motor tics can be simple, abrupt movements such as eye blinking, head jerks, or shoulder shrugs, or more complex behaviors such as facial expressions or arm gestures. Vocal tics can vary from simple throat-clearing sounds to more complex speech, including obscenities (Leckman and Cohen 2002). Tics ordinarily appear during childhood or early adolescence. They may be transient or chronic. Although twin and family studies indicate that genetic factors are involved in the etiology of tic disorders (Pauls and Leckman 1986), these disorders are also exacerbated by stress. In the rare (5–30 cases per 10,000 children, 1–2 cases per 10,000 adults) (American Psychiatric Association 2000) prototype disorder, Tourette's disorder, there are both motor and vocal tics, but either may also occur alone. Tics are up to three times more common in boys than in girls. Tourette's disorder is often seen in association with obsessive-compulsive disorder. Another motor abnormality of children that is unrelated to a general medical disorder is characterized by repetitive, seemingly driven, and nonfunctional motor behavior, such as hand shaking or waving or body rocking. The movements may also cause bodily injury, such as in head banging, self-biting, picking at the skin, or hitting one's own body. The so-called stereotyped movement disorders may be associated with mental retardation. Stereotyped movements may also be precipitated by stressful events and may be persistent or may subside after adolescence. The motor movements are similar to those seen in pervasive developmental disorders, but in stereotyped movement disorders, severe social skills and communication deficits are absent. Boys tend to have head banging as a symptom, whereas in girls self-biting may be more prevalent.

**Psychosexual Problems**

Interest in sexuality and sexual play are common in childhood. Sexual activities between children may be heterosexual or homosexual. The concept of a sexual identity as a boy or as a girl has usually developed by the age of 3 years (Ehrhardt and Meyer-Bahlburg 1981). Occasional cross-gender behavior in dressing or play also occurs in many normal children. When a child, usually a boy, actually develops a strong and persistent preference to be the other sex, the child has a gender identity problem. Such children may insist that they are the opposite sex, dress and play as if they are, and prefer friends of the other sex. They may also repudiate aspects of their own sex, such as having a penis. Most children with a gender identity disorder no longer report cross-gender identification or discomfort with or sense of inappropriateness in gender role by adolescence (American Psychiatric Association 2000).

Table 29–6 summarizes the estimated prevalence and sex distribution of DSM-IV-TR mental disorders seen in children.

Problems of Adolescence

Adolescence is the period of life between puberty and 19 years. For the great majority of children, the physiological events of puberty signify the end of childhood. Achievement of financial independence from the family of origin through work and formation of love relationships outside the family usually signify the end of adolescence and the beginning of adulthood. In the modern world, these goals may not be attained until the early or middle 20s or later. There are many important developmental phases in adolescence. Although moody, confused, and rebellious “adolescent turmoil” is no longer considered the norm for young people, some emotional troubles are fairly common. These may turn out to be symptomatic of nothing more than the stresses and strains of normal development, or they may be the early signs of significant psychological disturbance.

Adolescent Development

Early in adolescence, children become more independent of parents and mature sexually. Passage through puberty can be stressful. In middle adolescence, children attempt to further their development of an independent identity, experiment with sexual behavior, develop intellectual capacities such as reason and abstraction, and acquire values and morals. In late adolescence, the task is separation, with the concurrent development of a plan for work and discovery of loving relationships outside the nuclear family.

Types of Problems

Common problems of adolescence are listed in Table 29–7. Rarely, schizophrenia may have a late adolescent onset. As might be expected, comorbidity is common among disorders of adolescence. Table 29–8 summarizes these patterns.

Table 29–7 Psychopathology in Adolescence

| Identity problems                        |
| Emotional problems                      |
| Behavioral problems                     |
| Problems in self-image and physical functioning |

Identity Problems

Identity issues are at the crux of adolescent development. Therefore, distress about issues concerning long-term goals, values, peer loyalties, sexual orientation and behavior, and lifestyle is common in this age group. Although most identity problems are worked through during adolescence without serious sequela, unresolved problems may indicate the presence of mood or anxiety disorders or form the nucleus for the development of behavioral or characterological problems in adulthood.
Emotional Problems

Depressive episodes are much more common in adolescents than in younger children, with girls more frequently affected than boys (Harrington 2002). From 2% to 10% of teenagers, develop a full-blown major depressive episode (Cicchetti and Toth 1995). Teenagers of ages 14–17 years have a suicide attempt rate of 8–9%, and major depression, especially among girls, is a commonly associated disorder (Shaffer and Toth 1995). Teenagers of ages 14–17 years have a sui-

Major depression in adolescents is frequently accompanied by anxiety, substance use, behavior (young men), and eating (young women) disorders (Rohde et al. 1991). ComorbiditY is associated with more suicidal behavior (Foley et al. 2006) and treatment seeking.

A common age at onset for panic disorder is late adolescence (Horwath and Weissman 2000). About 1 in 200 adolescents may develop panic disorder (Lewinsohn et al. 1993). Panic disorder is characterized by sudden, unexpected panic attacks, which consist of a feeling of intense fear and a constellation of characteristic symptoms, such as palpitations, sweating, trembling, shortness of breath, choking, chest pain, nausea, dizziness, paresthesias, hot flashes, and feelings of going crazy or of dying. Panic disorder is more common among young women than young men. The course tends to be chronic, with waxing and waning of symptoms. Follow-up studies suggest that about one-third to one-half of affected people can be healthy and living normal lives, despite fluctuating or recurring symptoms (Pine 2000). Panic attacks among adolescents may be risk factors for developing other anxiety disorders or substance use disorders in young adulthood (Goodwin et al. 2004).

Social phobia also has a common onset in the teens (Schneier et al. 1995). Between 1% and 2% of teenagers may be affected (McGee et al. 1990 Cohen et al. 1993a). Fears of being humiliated or embarrassed in front of others may develop abruptly after a humiliating experience or may develop more gradually, in the context of a childhood history of social inhibition or shyness. In adolescents, social phobia may lead to poor school performance, avoidance of dating, and general social isolation. The duration is frequently lifelong (Table 29–9), although the severity of symptoms may fluctuate depending on life’s demands. By early-to-middle adult life, a limited social phobia, such as in speaking in front of a group, may become a more generalized and pervasive pattern of social inhibition, feelings of inadequacy,

*Other anxiety disorders such as separation anxiety disorder or generalized anxiety disorder may also occur.

*Comorbidity with other personality disorders, such as dependent personality disorder, and with mood and anxiety disorders is likely.
and hypersensitivity to negative evaluation characteristic of avoidant personality disorder (Skodol et al. 1995). In the community, social phobia is more common among women, although more men may seek treatment for it.

Obsessive-compulsive disorder has a modal age at onset between 6 and 15 years for boys and may affect as many as 2% of adolescents (Whitaker et al. 1990, Flament et al. 1988). Obsessive-compulsive disorder is characterized by persistent and intrusive anxiety-provoking thoughts. The obsessions of children and adolescents most often involve contamination, danger to self or others, symmetry, or moral issues (Rapoport and Swedo 2002). A person may perform repetitive behaviors, such as hand washing, ordering, or checking, or mental acts, such as praying, counting, or repeating words. Compulsive behaviors are performed rigidly, according to rules that are aimed at reducing anxiety or preventing something from happening. Among children and adolescents, rituals are more common than obsessions; washing rituals are the most common. Predominant symptoms often change over time. Symmetry and counting are common during grade school, excessive washing occurs frequently in early adolescence, and thoughts and behaviors with sexual themes arise in later adolescence. The course of obsessive-compulsive disorder is chronic, with waxing and waning of symptoms. In a 2-year follow-up of adolescents, symptoms and impairment persisted (Berg et al. 1989). As many as 30-50% of adult patients with obsessive-compulsive disorder report a childhood or adolescent onset (Karno and Golding 1991, Carter et al. 1995).

Posttraumatic stress disorder may become a persistent, chronic problem for adolescents in the absence of treatment (Goenjian et al. 2005). The occurrence of new traumatic events is a negative prognostic indicator (Perkonigg et al. 2005). Israeli adolescents (especially boys) exposed to recurrent terrorism have been found to engage in high levels of risk-taking behaviors, raising the possibility of a cycle of traumatic stress and post-traumatic stress symptomatology (Pat-Horenczyk et al. 2007).

Adolescent anxiety and depressive disorders result in a two- to three-fold risk anxiety and depressive disorders in young adulthood (Pine et al. 1998). The continuity effects are relatively nonspecific, except for simple and social phobia that persist. Even though most adolescent emotional disorders disappear by young adulthood, most adult disorders are preceded by adolescent disorders.

**Behavior Problems**

Experimentation with psychoactive substances is common in adolescence. More than 50% of 14-year-old boys and girls have had experience in drinking alcohol (Johnston et al. 1993). Although use of most substances of abuse is apparent for adolescents, alcohol, tobacco, and marijuana are the drugs of choice, and overall drug use by adolescents increased in the 1990s, with one-half to three-quarters of older adolescents having taken an illicit drug at some time (Weinberg et al. 2002). Initially, pathological drug use in the teens is in the form of episodes of intoxication, that is, clinically significant, maladaptive behavioral and physiological changes secondary to recent substance ingestion. Eight percent of eighth-graders, 18% of tenth-graders, and 30% of twelfth-graders reported that they had been intoxicated with alcohol in the past month (Johnston et al. 1993). The maladaptive changes of intoxication may include inappropriate sexual or aggressive behavior; mood lability; impaired judgment or increased risk taking; or impaired social, academic, or occupational functioning. Substance withdrawal is rare in adolescence, but it may occur if the drug has been taken in sufficiently high quantities for a sufficiently long time. Substance abuse or dependence (i.e., maladaptive patterns of substance use leading to social, occupational, legal, or physical problems) may also develop in adolescence, although an early onset of these types of problems usually suggests additional conduct problems. Most substance-related problems are more common in boys than in girls. In addition, there is ample evidence for a gateway effect—that is, use of a drug such as marijuana can frequently lead to use of more harmful drugs, and heavy use of marijuana significantly increases the likelihood of progressing to “harder” drugs (Rutter 2002b).

Recurrent substance intoxication often leads to substance abuse. Although the adverse social consequences of substance abuse often remain relatively stable over time (Helzer 1994), abuse evolves into dependence most commonly with drugs that have a high potential for the development of tolerance, withdrawal, and patterns of compulsive use. These substances include alcohol, cocaine, opioids, and sedative, hypnotic, and anxiolytic drugs. The course of substance dependence is extremely variable, ranging from complete remission after successful treatment or the development of a life-threatening physical ailments secondary to drug use to chronicity. Early use of drugs or alcohol by adolescents predicts persisting problems (Robins and Przybeck 1985). Use of drugs by adolescents has been shown to be associated with elevated rates of delinquency, unemployment, divorce, and abortions in young adulthood (Kandel et al. 1986). Co-occurring mental disorders, such as mood disorders and personality disorders, increase the risk of poor outcomes.

Conduct problems of adolescence may be a continuation of childhood problems or may arise de novo during the teenage years. Estimates of the prevalence of conduct disorder from general population studies range from less than 1% to more than 10% (American Psychiatric Association 2000). Conduct problems of adolescence are more serious than conduct problems of childhood. The greater freedom, independence, and physical strength of adolescents increase the risk that aggressive or destructive behavior will harm others. Conduct problems that commonly emerge during adolescence include burglary, mugging, armed robbery, rape, and the use of knives and guns in arguments and fights.

Persistence of childhood conduct problems into adolescence and evolution of more severe aggressive and destructive behaviors portend a continuation of antisocial behavior and substance abuse in adult life (Cohen et al. 2007, Myers et al. 1998). Persistent deviant peer group involvement in boys can be predicted by a behavioral profile of hyperactivity, fearlessness, and low prosocial behaviors as early as kindergarten (Lacourse et al. 2006). Premature menarche leading to affiliation with older, more deviant peers has been associated with higher rates of conduct disorder in adolescent girls (Burt et al. 2006). Onset of conduct disorder in adolescence, however, suggests a better prognosis (Robins 1966). Conduct disorder has also been shown to be associated with premature death.
from violent causes (Rydelius 1988, Yeager and Lewis 1990) or substance abuse (Laub and Voilant 2000).

Externalizing disorders (conduct disorder, adult antisocial behavior, alcohol dependence, and drug dependence) share a common underlying inheritable vulnerability (Hicks et al. 2004). Neurobehavioral disinhibition in affect, behavior, and cognition in childhood has been shown to predict substance use disorder in adolescence (Tarter et al. 2003). Genetic vulnerability to heavy drinking is greater in men than in women (King et al. 2005). Shared environmental influences have also been implicated that are stronger for initiation and use of substances than for problem use (Kendler et al. 2003, Rhee et al. 2003). Unique environmental experiences may determine which type of substance a person will use or misuse.

Teenage boys are particularly vulnerable to developing pathological gambling. Adolescent gamblers are more likely than nongamblers to have substance use disorders and depression (Lynch et al. 2004). Gambling behavior can become an addiction with greater and greater amounts of time and money spent on gambling, with deleterious financial, social, and sometimes legal consequences. Personality characteristics of high negative emotionality, low constraint, risk taking, and impulsivity are shared by individuals with pathological gambling and those with substance use disorders (Slutske et al. 2005). Gambling may be regular or episodic, but the course is chronic. Gambling behavior increases during times of stress. Pathological gambling frequently becomes associated with mood, anxiety, and substance use disorders (Roy et al. 1988) by middle age, with resultant reduced quality of life (Scherrer et al. 2005). The relationship between pathological gambling and major depression in men is largely influenced by overlapping genetic factors (Potenza et al. 2005).

Trichotillomania is the behavior of recurrent pulling out of one’s own hair (Swedo 1993). Common areas of the body for hair pulling are the scalp, eyebrows, eyelashes, and beard. There is an increasing sense of tension that is relieved after hair pulling. The behavior shares features of both impulsive and compulsive behavior problems (Skodol and Oldham 1996). Trichotillomania appears to be more common among girls than boys. The peak ages at onset are between 5 and 8 years and again at about the age of 13 years. The symptoms may be continual with significant hair loss resulting or may be episodic. Trichotillomania is commonly associated with mood, anxiety, and substance use disorders (Swedo et al. 1989b, Christenson et al. 1991).

Problems in Self-image and Physical Functioning
Disturbances in body image and eating behavior have peak ages at onset during adolescence and early adulthood. Anxiety disorders in general and obsessive-compulsive disorder in particular are common in the childhood histories of individuals with eating disorders (Kaye et al. 2004). Genetic, personality, perinatal, and socioenvironmental factors have been implicated in the development of eating disorders (Bulik et al. 2006, Favaro et al. 2006, The McKnight Investigators 2003, Wade et al. 2004). Eating disorders are more common in white than in black women (Striegel-Moore et al. 2003).

A girl with anorexia nervosa (90% of those with eating disorders are female) refuses to maintain her body weight above minimally normal and has an intense fear of becoming fat. In addition, she has a disturbance in the way her weight and body shape are experienced, such that she denies the seriousness of her low weight and places excessive importance on her weight and shape for self-esteem. Girls with anorexia nervosa become amenorrheic. They may also engage in binge eating and purging behavior (Halmi 1985). The prevalence of anorexia nervosa among females is approximately 0.5% (American Psychiatric Association 2000). Anorexia nervosa occurs most commonly in industrialized countries (Pate et al. 1992), where the ideal of physical attractiveness is to be thin, and may be increasing over time (Lucas et al. 1991). The onset is often after a stressful life event. Patients with anorexia nervosa may experience episodes of major depression (Herzog et al. 1992) or have obsessions and compulsions about issues in addition to food, weight, and body shape. The course of anorexia nervosa is variable, ranging from a single adolescent episode to a chronic, lifelong, and deteriorating course. Although persistence of the diagnosis of anorexia nervosa was recently found to be only 10% over a 12-year follow-up period, low body weight and perfectionism were common and rates of comorbid mood, anxiety, and substance use disorders were high (Sullivan et al. 1998). Factors associated with a good prognosis include an early age at onset, hysterical personality, good parent-child relationship, early treatment, and high socioeconomic status. Factors associated with a poor prognosis include bulimia, vomiting, and compulsivity (Steinhausen et al. 1991). Mortality in serious cases may be 10% (American Psychiatric Association 2000). Mortality may be predicted by low body weight (Hebebrand et al. 1997), severity of alcohol use (Keel et al. 2003), and delay in receiving treatment (Millar et al. 2005).

In bulimia nervosa, there are recurrent episodes of binge eating in which large amounts of food are consumed in an out-of-control mode, accompanied by compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or enemas; fasting; or excessive exercise. Bulimia nervosa is more common than anorexia nervosa; it is estimated to occur in 1–3% of women (American Psychiatric Association 2000). Childhood adversities, particularly maladaptive behavior on the part of fathers, contribute to the development of eating disorders in adolescence or early adulthood (Johnson et al. 2002). Patients with bulimia nervosa may also have mood disorders, problems with substance abuse or dependence, or other problems of impulse control, which predict future outcome (Keel et al. 2000). The mean age at onset is slightly later for bulimia nervosa than that for anorexia nervosa. The behavior usually persists for several years, at least, and may be chronic or intermittent. In a recent community-based study, between one-half and two-thirds of girls with bulimia nervosa had some symptoms of an eating disorder over a 5-year follow-up period. Each year a third remitted and a third relapsed (Fairburn et al. 2000). In clinical samples, 50% may recover after 5–10 years (Keel and Mitchell 1997). After 10 years, about 10% of patients may still have bulimia nervosa, although an additional 20% will have some continuing symptoms. Duration of the disturbance before seeking treatment, substance abuse (Keel et al. 1999), greater body image disturbance, and worse psychosocial functioning (Keel et al. 2005) predict a worse prognosis. Persistence of disturbed eating behaviors into
early adulthood is accompanied by the development of personality disorders in many cases. Bulimia nervosa has been shown to be associated with borderline personality disorder in contrast with anorexia nervosa, which was found to be associated with avoidant personality disorder (Skodol et al. 1993). Binge-eating disorder (without purging) has also been documented to be a chronic disorder (Pope et al. 2006).

Although adolescents tend to sleep late, excessive daytime sleepiness may become a problem during adolescence. Excessive sleepiness may indicate the onset of narcolepsy, a rare disorder characterized by sleep attacks, accompanied by cataplexy (sudden, bilateral loss of muscle tone), and/or hypnagogic or hypnogenic hallucinations or sleep paralysis (Regestein 1994a). The excessive sleepiness of narcolepsy is persistent over time. Poor nocturnal sleep may develop later in middle age. Persons developing narcolepsy may have had a childhood history of a parasomnia, such as sleepwalking disorder, or an elimination disorder, such as enuresis. Comorbidity with major depressive disorder, dysthymic disorder, generalized anxiety disorder, and substance-related disorders on a concurrent or lifetime basis is also common (American Psychiatric Association 2000). There are equal numbers of males and females with narcolepsy.

A preoccupation with an imagined or exaggerated defect in appearance may develop in adolescence. Unlike the normal concerns of adolescents with their physical appearances, excessively time-consuming concerns that cause great distress or interfere with functioning suggest body dysmorphic disorder. Common complaints involve imagined or slight defects of the face or head or preoccupation with the shape or size of some body part (Phillips 1991). The obsessive preoccupation with the perceived defect and frequently accompanying mirror checking and excessive grooming behaviors suggests a continuity with obsessive-compulsive disorder or with the weight and shape preoccupations and accompanying behaviors of anorexia nervosa. The course of body dysmorphic disorder is chronic, at least over the short term (Phillips et al. 2006). Persons with the disorder may seek repeated and unnecessary surgical corrections of their perceived disfigurements, which rarely result in improvements in their conditions (Hollander and Phillips 1993). Suicidal ideation and attempts are common (Phillips and Menard 2006). Men and women are equally likely to be diagnosed with the disorder.

Table 29–10 summarizes the estimated prevalence and sex distribution of DSM-IV mental disorders commonly seen in adolescents.

**Problems of Early Adulthood**
The period between the ages of 20 and 30 years is commonly referred to as early adulthood.

**Early Adult Development**
Developmental tasks of early adulthood include achieving emotional and financial independence from parents and forming intimate relationships with people outside the family of origin. Stage-specific stressors include leaving home, education and career choice, in some cases service in the armed forces, finding and maintaining employment, courtship and marriage, and sexual relations, among others.

**Types of Problems**
Problems of young adulthood fall mostly into the categories listed in Table 29–11. By the end of early adulthood, people have passed through the ages of greatest risk for first onset of the majority of recognized mental disorders. Comorbidity between disorders becomes the rule rather than the exception. In a population survey in the US covering a 12-month period, of those who met criteria in the prior year for a mental disorder (26% of the sample), 22% carried two diagnoses and 23% had three or more diagnoses (Kessler et al. 2005b).

The relationships between comorbid “disorders” are complex. Whether they indeed represent independent entities with distinctive etiologies, pathogenetic mechanisms, and outcomes, or merely reflect different ways in which fundamental psychopathological disturbances are manifest over time, between sexes, or across aspects of psychological functioning remains to be determined. In some cases, one disorder is clearly antecedent to another. Examples include disorders of childhood, such as separation anxiety disorder or conduct disorder, that evolve into adult versions—in these cases, panic disorder with agoraphobia or antisocial personality disorder, respectively. Sometimes, as in the case of ADHD, residual symptoms persist and form the basis for developing problems such as substance abuse or personality dysfunction. At other times, a second disorder may develop as a consequence of a primary disorder—in reaction to it or as a complication. Examples include major depressive disorder developing after a person has been incapacitated by panic disorder with agoraphobia, or sedative, anxiolytic, or alcohol abuse developing because the person attempted to self-medicate for the condition. Alternatively, disorders appear more or less contemporaneously and reflect an underlying diathesis or vulnerability. Thus, patients present with several disorders, all suggestive of a problem of generalized impulsivity, such as bulimia nervosa, a substance use disorder, and an impulse control disorder (e.g., kleptomania). Personality disorders often develop in the context of underlying traits affecting specific capacities such as impulse control or interpersonal relatedness, as dysfunction becomes widespread.

Table 29–12 summarizes patterns of comorbid mental disorders in early adulthood.

### Emotional Problems

Although disturbances in mood can occur at any age, the peak ages of onset of mood disorders are probably in the 20s. Mood disturbances may be acute and episodic or insidious and chronic. They may be relatively mild or severe and may be accompanied by psychotic features or suicidal behavior. The most common mood disorders are major depressive disorder, dysthymic disorder, bipolar disorder, and cyclothymic disorder.

Major depressive disorder is characterized by episodes of severe depression that impair functioning. The lifetime risk for major depressive disorder is estimated to be between 10% and 25% and the point prevalence in adult women from 5% to 9% (American Psychiatric Association 2000). About twice as many women are affected as men. Heritability of major depression is higher in women than in men (Kendler et al. 2006). Initial episodes of major depressive disorder are often precipitated by a psychosocial stressor. Men and women both experience stressful life events—men more legal and work-related events and women more interpersonal events—prior to the development of a major depressive episode and appear equally sensitive to them (Kendler et al. 2001). More than 50% of people who have a major depressive episode have a second episode, and as the number of episodes increases, the likelihood of having subsequent episodes (Solomon et al. 2000) and the severity of the episodes also increase (Maj et al. 1992). The time period between episodes generally decreases with recurrences. In all, about 85% of recovered patients will experience a relapse over 15 years (Mueller et al. 1999). About two-thirds of episodes of major depressive disorder resolve completely, about 40% within 3 months and 60% within 6 months (Keller et al. 1992b, Coryell et al. 1994). Full remission would be characterized by absence of symptoms, return to usual self and usual level of functioning, and the presence of features of positive mental health, such as optimism and self-confidence (Zimmerman et al. 2006). The average duration for an episode is about 20 weeks (Solomon et al. 1997). Chronicity or partial remission characterizes the others.

Over 12 years of follow-up, most patients will have been symptomatic at some level, although subsyndromal symptoms are much more common and lasting than full-blown
episodes (Judd et al. 1998). Incomplete recovery from an episode appears to predict a more severe, relapsing, and chronic course (Judd et al. 2000b), as do psychotic symptoms during the initial episode (Coryell et al. 1996). Comorbid depression and anxiety also predicts a more chronic course (Merikangas et al. 2003). Despite this tendency toward chronicity, people continue to recover from depressive episodes, even those characterized by a lengthy period of illness (Mueller et al. 1996). The course of major depressive disorder is similar for men and women (Simpson et al. 1997). Persistent depressive symptoms are associated with persistent impairment in functioning, proportional to the severity of the symptoms (Judd et al. 2000a). Traits of personality that make a person vulnerable to major depression (neuroticism, low self-esteem, and poor coping skills) persist after remission and psychosocial disability after remission often reflects poor premorbid functioning (Orr et al. 2004a, 2004b). Major depression has been associated with increased mortality from suicide and from natural causes (Osby et al. 2001, Pennx et al. 2001). Suicide in major depression is associated with pessimism, impulsive/aggressive personality traits, prior suicide attempt, and comorbid substance use disorders, particularly involving alcohol and nicotine (Dumais et al. 2005, Oquendo et al. 2004).

Nearly 5–10% of persons with major depressive episodes develop bipolar disorder. Dysthymic disorder sometimes precedes the development of major depressive disorder. Panic disorder, obsessive-compulsive disorder, both anorexia nervosa and bulimia nervosa, substance-related disorders, and several different personality disorders are often found in association with major depressive disorder.

Dysthymic disorder is characterized by milder depressive symptoms that are chronic. They are more often cognitive (e.g., low self-esteem, pessimism, feelings of inadequacy) than vegetative (e.g., insomnia, loss of appetite) (Keller et al. 1995). It has an insidious onset, usually persists for years (although symptoms may fluctuate), and often is complicated by episodes of superimposed major depressive disorder (the so-called double depression) (Keller and Shapiro 1982, Klein et al. 2000). Dysthymic disorder is about half as common as major depressive disorder. The sex ratio for dysthymic disorder is 1:1. Persons with dysthymic disorder with or without concomitant major depressive episodes had a poorer outcome than persons with major depression alone during a 2-year follow-up period (Wells et al. 1992). Dysthymic disorder is often found in persons with personality disorders and substance use disorders.

Manic episodes characterize bipolar I disorder. Manic episodes are periods of persistently elevated, expansive, or irritable mood. Bipolar I disorder is relatively rare compared with major depressive disorder, affecting 0.4–1.6% of persons on a lifetime basis (American Psychiatric Association 2000). Bipolar I disorder is equally common in men and women. The first episode of what eventually becomes bipolar I disorder is more likely to be a depressive episode in women than in men, whose initial episode is more likely to be manic, and age at onset of manic episodes is earlier in men (Kennedy et al. 2005). About 90% of persons with bipolar I disorder have recurrent episodes (Keller 1985, Keller et al. 1993). Patients with bipolar I disorder have more lifetime episodes, in general, than patients with recurrent major depressive disorder (Winokur et al. 1993). Subsyndromal symptoms between episodes may occur in 50% or more of patients and substantially increase the risk of relapse into full mood episodes (Keller et al. 1992a, Keck et al. 1998, Tohen et al. 2003). From 15% to 25% of patients with bipolar I disorder have persistent mood disturbance and functional impairment (Winokur et al. 1993, Carlson et al. 1974). The course of both Bipolar I and II is dominated by more depressive episodes than manic or hypomanic phases, and the depression is equally or more impairing than the mania (Judd et al. 2005). Rapid cycling between manic and depressive episodes is associated with increased depressive morbidity and serious suicide attempts (Coryell et al. 2003) and a generally more severe course of illness (Schneck et al. 2004). A small number of people may have unipolar mania over the course of many years, without depressive episodes (Solomon et al. 2003).

If a person has hypomanic episodes characterized by shorter duration of mood elevation and less impact on functioning than in a manic episode, the person is said to have bipolar II disorder (Dunner 1983). Mixed hypomanic (euphoric and depressive symptoms occurring together are common in women with bipolar disorder (Suppes et al. 2005). Bipolar II and other subthreshold bipolar disorder are more common than bipolar I in the general population (Merikangas et al. 2007). Bipolar disorders are often accompanied by anxiety, eating, and substance-related disorders and ADHD, which are generally related to a poorer prognosis (Nolan et al. 2004, Simon et al. 2004). Substance dependence is associated with recurrence of mood episodes (Tohen et al. 1990). Bipolar II disorder may be comorbid with borderline personality disorder.

Cyclothymic disorder is characterized by a chronic mood disturbance with numerous periods of hypomanic and depressive symptoms that are not as severe as in bipolar I disorder or major depressive disorder. Persons with cyclothymic disorder are at increased risk for a bipolar disorder.

Although several anxiety disorders have their onset most often in childhood or adolescence, as previously described, others have increased risk for onset in early adult life. In particular, many cases of acrophobia (fear of heights) and situational phobias, such as of elevators, flying, or closed places, develop in early adulthood (American Psychiatric Association 2000). Women, previously married people, and the unemployed and disabled are more likely to have some form of panic disorder (Kessler et al. 2006). Obsessive-compulsive disorder has a later age at onset in women than in men, during the 20s rather than the teens. Acute stress disorder and PTSD can occur at any age but are prevalent in young adults.

Disorders such as panic disorder, other specific phobias, social phobia, and generalized anxiety disorder, which are more likely to begin in childhood or adolescence, may persist or recur during early adult life. The median onset age of anxiety disorders is 11 years; anxiety disorders are more common in women (Kessler et al. 2005a). The lifetime prevalence of panic disorder in the adult population is estimated to be 4.7% (Kessler et al. 2005a); the 1-year prevalence rate is 2.7% (Kessler et al. 2005b). Phobias are common in the community. The lifetime rate is estimated to be 12.5% (Kessler et al. 2005a) and the 1-year rate 8.7% (Kessler et al. 2005b). The lifetime prevalence rate of social phobia is
12.1% (1 year: 6.8%), generalized anxiety disorder is 5.7% (1 year: 3.1%), and obsessive-compulsive disorder has an estimated lifetime prevalence of 1.6% (1 year: 1.0%) (Kessler et al. 2005a, 2005b). Episodes of panic disorder may be precipitated by disruptions in interpersonal relationships; social phobia may occur after new demands in school or the workplace for speaking to a group. Childhood phobias that persist into adulthood remit infrequently (American Psychiatric Association 2000). Rates of remission of panic disorder over 5 years are about 40% in both men and women, although recurrence rates are higher among women (Yonkers et al. 1998). Women with early adult-onset panic disorder tend to have attacks that persist into older age (Regier et al. 1988). Comorbidity with other anxiety disorders is common for all types of anxiety disorders. The course of most anxiety disorders is chronic, with social phobia having the smallest probability of recovery (Bruce et al. 2005). High percentages of people with anxiety disorders also suffer from mood disorders and may develop substance-related disorders as a result of efforts to treat their anxiety with alcohol or medications. Comorbidity worsens the clinical course of anxiety disorders. Anxiety disorders are independent risk factors for subsequent suicide attempts (Sareen et al. 2005).

Although psychological reactions to extremely stressful events can occur, like the events themselves, at any age, much of what is known about these reactions has been learned from populations of young adults. These populations include soldiers in combat (Kulka et al. 1990, Solomon and Mikulincer 2006), refugees (Kinzie et al. 1990, Weine et al. 1998), and community subjects who have experienced crime victimization (Breslau et al. 1991, 1998), child abuse (Widom 1999), natural or human-made disasters (Havenaar et al. 1997, Goenjian et al. 2000), terrorism (Shalev and Freedman 2005) or life-threatening injury, such as traffic accidents (Ursano et al. 1999), or illness (Helzer et al. 1987, Davidson et al. 1991).

Immediately after an event in which a person experiences or witnesses actual or threatened death or serious injury or threat to physical integrity, which arouse feelings of helplessness, fear, or horror, an acute stress reaction may occur. These reactions are characterized by (1) dissociative symptoms, such as feeling numb or detached, derealization, or depersonalization; (2) reexperiencing symptoms, such as recurrent images, thoughts, dreams, or flashbacks of the traumatic event; (3) avoidance of stimuli that arouse recollections of the trauma; and (4) symptoms of hyperarousal, such as hypervigilance, exaggerated startle response, and difficulty in sleeping. Acute stress reactions resolve within a month of a stressor and may serve an adaptive function, limiting painful thoughts and feelings associated with the stressor (Kooiman et al. 1995). When the symptoms persist, the disorder is known as PTSD. Dissociative symptoms are less prominent in PTSD than in acute stress disorder. PTSD may also have a delayed onset—months or even years after the traumatic event. The lifetime prevalence of PTSD in the US community population has been found to be 6.8% (Kessler et al. 2005a).

The severity, duration, and proximity of a person’s exposure to a traumatic event influence the risk of developing either an acute stress disorder or PTSD (March 1993). Acute stress reactions which do not resolve (Classen et al. 1998), peritraumatic dissociation (Shaley et al. 1996) or emotional numbing in response to the stressor (Epstein et al. 1998) predict later PTSD. Social support, family history, childhood experiences, personality variables, such as hostility and low self-efficacy (Heinrichs et al. 2005), neurocognitive deficits (Kremen et al. 2007, Parslow and Jorm 2007), and preexisting mental disorders also affect risk. Men and women appear equally vulnerable.

Re-experiencing, avoidance, and hyperarousal symptoms may fluctuate over the course of PTSD. Intrusion symptoms may be more common early in the course and avoidant symptoms may become more common later (Blank 1993). About one-half of cases resolve in a few months; others may persist for years. PTSD is frequently accompanied by mood, psychoactive substance use, personality, and other anxiety disorders (Davidson and Foa 1991). PTSD has been shown to increase risk for later coronary heart disease (Kubzansky et al. 2007).

Dissociative disturbances may occur in the absence of re-experiencing or avoidance symptoms, often in response to severe stress (Spiegel and Cardena 1991). Dissociative states all involve isolation of memory and emotions from normal states of consciousness, disturbance in sense of identity or sense of self, and experiences of intense absorption or focused concentration (Putnam 1995). The exact prevalences of dissociative amnesia, fugue (inability to recall one’s past, unexpected travel), depersonalization, and identity (multiple personality) disorders are not known, but all are probably relatively rare. The course of dissociative problems is usually chronic but fluctuating, with exacerbations occurring in association with episodes of stress or trauma. Dissociative disturbances may be more common among women.

Dissociative amnesia is seen in association with conversion disorder, mood disorders, or a personality disorder. Fugue states may be seen, in addition, in PTSD and in association with substance-related disorders. Depersonalization can be seen in substance-related disorders and hypochondriasis. Persons with dissociative identity disorder may also have mood disorders, eating disorders, sexual disorders, substance-related disorders, sleep disorders, or borderline personality disorder (American Psychiatric Association 2000).

Milder, time-limited reactions to stressors of any severity may also occur. These are common occurrences that might follow the breakup of a romantic relationship or the loss of a job. The symptoms may be of depression, anxiety, or disturbance of conduct. They cause temporarily decreased performance at school or work or impairment in social relationships. Provided that the consequences of the stressor are resolved (i.e., the person resumes dating or obtains a new job), the course of the symptoms and impairment should be less than 6 months.

**Behavior and Adaptive Functioning**

Problems with various types of impulsive behaviors and problems with adaptive functioning in general seem particularly prone to become manifest in early adulthood. These problems may develop, in part, secondary to the increased stresses of movement away from the protective environments of school and family that characterize the period.

Although experimentation with substances ordinarily begins in adolescence and some personal, social, or legal problems secondary to maladaptive patterns of use (abuse)
may have already occurred, the full syndrome of dependence on alcohol or other substances may not emerge until the 20s. Dependence on substances is characterized not only by symptoms of physiological dependence, such as tolerance or withdrawal, but also by a pattern of loss of control over substance use (Rounsaville and Kranzler 1989). The prevalence of substance abuse or dependence varies widely depending on the substance. Alcohol dependence and nicotine dependence are common, with lifetime prevalence estimates ranging between 15% and 20%. Amphetamine and cannabis dependence affect 1.5–5% of the population and opioid dependence less than 1% (American Psychiatric Association 2000). The course of substance dependence is variable, and depends somewhat on the class of substance and its route of administration. In general, frequent substance intoxication may lead to repeated episodes of substance abuse, which can develop into substance dependence, although the frequency of progression is variable. For example, in three 4- to 5-year follow-up studies, the range of alcohol-abusing men who progressed to alcohol dependence was from 3.5% (Schuckit et al. 2000, 2001) to 30% (Hasin et al. 1990). Episodes and recurrences are commonly precipitated by stressors or accompany episodes of other mental disorders, such as major depressive disorder. For drugs of abuse, men are more likely to have substance-related problems than are women.

A childhood history of conduct disorder or ADHD frequently precedes the development of substance abuse or dependence. A history of mood or anxiety disorders is common in persons with nicotine dependence. Concurrent antisocial personality disorder is common in people with substance use disorders that involve illegal and expensive drugs such as cocaine, heroin, or amphetamines. Substance use disorders can develop in the context of PTSD and often complicate the course of mood, anxiety, and psychotic disorders. Co-occurring mental disorders often lead to further complications secondary to substance use and a poorer overall prognosis.

Other problems of impulse control involving assaultive acts or destruction of property (intermittent explosive disorder), fire setting (pyromania), or stealing (kleptomania) may begin in early adult life (McElroy et al. 1995). Social gambling may progress to become pathological gambling.

Of major significance in the 20s is the stabilization of patterns of perceiving, relating to, and thinking about the environment and oneself that we call personality. Also, however, in the 20s, the potential for the development of inflexible and maladaptive traits that cause distress or interfere with effective social and occupational functioning may arise. Thus, personality disorders may become evident.

The standard guidelines for the diagnosis of personality disorders refer to a pattern of inner experience and behavior that has an onset in adolescence or early adulthood and is stable and of long duration. Some traits or behaviors that are forerunners of adult personality disorders, such as mood lability and impulsivity for borderline personality disorder, are often evident in childhood or adolescence (Rey et al. 1995, Bernstein et al. 1996). Personality disorder-related traits appear to decline from adolescence into early adulthood (Johnson et al. 2000a, Lenzenweger 1999, Lenzenweger et al. 2004), but those who develop personality disorders have elevated traits as adolescents. A variety of childhood and adolescent mental disorders are associated with the development of personality disorders in young adults, including major depressive disorder, childhood conduct disorder, anxiety disorders, and childhood anxiety disorders (Kasen et al. 1999, 2001). Because adolescent development is often a period of rapid growth and change, it is difficult to conceptualize a stable personality pattern during the teenage years. However, adolescents with personality disorders are at risk for violence and criminal behavior, as well as major mental disorders and suicidality in adulthood (Johnson et al. 1999, 2000b). Evidence of personality pathology in adolescence is also significantly associated with later development of substance use disorders (Cohen et al. 2007).

Personality disorders presumably arise from interactions between a person’s temperamental traits and predispositions and his or her experiences with parents, siblings, peers, and others (Millon and Davis 1995). Innately high versus low levels of arousal, activity, and sociability may either become reinforced by life’s experiences to harden into exaggerated and inflexible personalities or be balanced by a fortuitous combination of chance and parental planning over the years leading to adulthood. Personality disorders show improvement over time despite the assumptions of stability in the definition of personality disorder (Grilo et al. 2004, Zanarini et al. 2006). Some criteria are more stable and trait like, while others appear to reflect behaviors that are situationally dependent and intermittently expressed (McGlashan et al. 2005; Zanarini et al. 2007). The prevalence of individual personality disorders ranges from about 2% to 3% for the more common varieties, such as schizotypal, antisocial, borderline, and histrionic, to 0.5–1% for the least common, such as narcissistic and avoidant (American Psychiatric Association 2000).

Personality disorders fall into three clusters (Table 29–13) that have some descriptive validity: the odd-eccentric cluster (paranoid, schizoid, and schizotypal), the dramatic-emotional cluster (antisocial, borderline, histrionic, and narcissistic), and the anxious-fearful cluster (avoidant, dependent, and obsessive-compulsive) (Kass et al. 1985). The disorders in each of the three clusters may share some underlying common vulnerability factors involving cognition, affect and impulse control, and behavioral maintenance or inhibition, respectively, and may have a spectrum relationship to certain syndromal mental disorders (Siever and Davis 1991). Thus, paranoid or schizotypal personality disorders may be observed to be premorbid antecedents of delusional disorders or schizophrenia; borderline personality disorder is seen in association with mood and anxiety disorders and with disorders of impulse control, such as bulimia nervosa, ADHD, or a substance use disorder; and avoidant personality disorder is seen with generalized social phobia. Comorbidity between personality disorders (Oldham et al. 1992) and related other mental disorders is substantial (Oldham et al. 1995). The presence of any personality disorder in the early 20s is associated with compromised quality of life a decade later (Chen et al. 2006), and severe personality disorders, such as schizotypal or borderline, are associated with high degrees of functional impairment and extensive utilization of mental health treatment resources (Skodol et al. 2002, Bender et al. 2001). Functional impairment in personality disorders may be more stable than personality psychopathology itself (Skodol et al. 2005). Patients
whose personality disorders persist are more impaired as young adults than those whose personality disorders remit (Skodol et al. 2007). Cluster A personality disorders and antisocial and narcissistic personality disorders are diagnosed more frequently in men than in women. Borderline, histrionic, and dependent personality disorders are diagnosed more frequently in women than in men.

**Disturbances in Physical Functioning**

Certain disturbances in physical functioning are likely to become manifest in early adult life. These include disturbances in sexual functioning, sleep disturbances, and some physical complaints that cannot be fully explained on the basis of a known general medical condition.

Disturbances of sleep, including both insomnia (Reynolds et al. 1994) and hypersomnia (Regestein 1994b), commonly develop in young adults. Insomnia and hypersomnia may occur in association with another mental disorder, a general medical condition, or use of a substance, or may be independent of other pathological conditions (primary). Insomnia is much more common than hypersomnia in association with other mental disorders, such as major depressive disorder, bipolar disorder, or a psychotic disorder. Sleep disorders related to another mental disorder are more common in women because of the parallel increased prevalence of mood and anxiety disorders among women (American Psychiatric Association 2000).

Primary insomnia often begins acutely after a period of psychosocial or medical stress. The common complaint of young adults is difficulty falling asleep. Women are more often affected than men. Because of conditioning and hyperarousal, a sleeping problem can become persistent. Some cases remit after resolution of the stressor; others are chronic or episodic for many years. Insomnia secondary to another mental disorder (e.g., schizophrenia, mood, and anxiety disorders) (Nozfinger 1994) or a medical condition (e.g., chronic obstructive pulmonary disease, asthma) (Sateia 1994) usually follows the course of the underlying disorder. The course of insomnia related to substances depends on the particular substance involved. Primary hypersomnia rarely resolves without treatment.

Certain disturbances characterized by physical complaints without known medical etiology have a high incidence rate in early adulthood. Specifically, conversion reactions, hypochondriasis, and somatization disorder can be first diagnosed in this age group.

Conversion disorder is a rare disturbance characterized by unexplained symptoms or deficits affecting voluntary motor or sensory functions. Conversion disorders are more common in women than in men (American Psychiatric Association 2000). Psychological stressors or conflicts invariably precede the initiation or exacerbation of the symptoms. The onset is usually abrupt and symptoms remit within 2 weeks. Recurrences are common, and a single recurrence predicts future problems. Paralysis and blindness have a better prognosis than tremor or seizures (Toone 1990).

Hypochondriasis is a preoccupation with fears of having or the belief that one has a serious disease. It is equally common in men and in women and has a general population prevalence of 1–5% (American Psychiatric Association 2000). The course is usually chronic, with waxing and waning of symptoms. Over a 4- to 5-year period, patients with hypochondriasis will show a decline in symptoms and an improvement in psychosocial functioning, but two-thirds will continue to have the disorder (Barsky et al. 1998).

Hypochondriasis is often seen in association with anxiety disorders (Barsky et al. 1994) or depression. Comorbid personality disorder suggests a poorer prognosis.

People with somatization disorder have multiple physical complaints involving pain, gastrointestinal symptoms, sexual symptoms, and pseudoneurological symptoms that cause them to seek repeated medical evaluations and treatments. The disorder is more common among women, with a prevalence estimated as 0.2–2.0% among women and less than 0.2% in men (American Psychiatric Association 2000). Initial symptoms, often menstrual complaints, are commonly present during adolescence, and the full syndrome is typically present by the age of 25 years (symptoms begin before the age of 30 years by definition). The course is chronic but fluctuating (Guze et al. 1986). Conversion disorder may progress to somatization disorder (Kent et al. 1995). Major depressive disorder, panic disorder, substance-related disorders, and cluster B personality disorders are frequently comorbid (American Psychiatric Association 2000).

Rarely, a person may intentionally produce or feign physical symptoms to become a patient, but not for obvious reasons. The so-called factitious disorders are more

common in men than in women. The course may be episodic or chronic. The onset usually follows a hospitalization for a bona fide general medical condition or another mental disorder. Severe personality psychopathology is usually present.

Psychosexual Problems
Sexual experimentation begins in adolescence and, although some adolescents may have ongoing sexual relations, sexual behavior becomes an expected part of life in the 20s. Thus, the 20s seem to be a common period for the onset of sexual dysfunctions. Premature ejaculation is a common problem in young men and is often present from their first experiences with intercourse. With further sexual experience and aging, most men learn to control and delay orgasm. Premature ejaculation may recur after a period of sexual abstinence or secondary to performance anxiety with a new partner. Vaginismus (involuntary spasm of the muscles of the vagina) is a problem that can affect young women having their first experiences with intercourse. Inhibited orgasm is also a problem of younger women; orgasmic capacity in women increases with age. Disorders of sexual arousal (e.g., deficient desire or excitement) usually develop during adulthood, after a period of normal sexual interest, in association with psychological distress, stressful life events, or interpersonal difficulties. The exact prevalence of the psychosexual dysfunctions is unknown, although problems with desire and orgasm are more common among women (Nathan 1986, Spector and Carey 1990). Psychosexual dysfunctions are likely to have significant adverse affects on marital and other interpersonal relationships.

Paraphilias are disorders of sexual aim. Persons with paraphilias are sexually aroused by fantasies, urges, and behaviors that involve non-human objects, suffering or humiliation, children, or other nonconsenting persons. Paraphilias include exhibitionism (exposure of genitals), fetishism (use of inanimate objects), frotteurism (touching or rubbing), pedophilia (sexual activity with children), sexual masochism (self-suffering), sexual sadism (sexual excitement derived from the suffering of others), transvestic fetishism (cross-dressing), and voyeurism (watching). Paraphilias have a usual age at onset from late adolescence into early adult life. Except for sexual masochism (male-to-female ratio of 20:1), paraphilias are almost never found in women. The actual prevalence of paraphilias is also unknown, but pedophilia, voyeurism, and exhibitionism are most commonly found in clinics specializing in their treatment (American Psychiatric Association 2000). Multiple paraphilias may coexist; when one subsides, another may emerge or become more prominent (Abel et al. 1988). Sexual dysfunctions and personality disorders may be comorbid.

Problems in Reality Testing
Problems in reality testing are reflected in abnormalities of speech, thinking, perception, and self-experience. They are suggestive of psychotic disorders such as schizophrenia. Although schizophrenia and its counterpart disorder of briefer duration, schizophreniform disorder, may have an onset in late adolescence (or in later adulthood), the most common age at onset is in early adult life. There is a distinct sex difference in median age at onset for the first psychotic episode of schizophrenia: for men the onset is in the early-to-middle 20s; for women the onset is in the late 20s. The lifetime prevalence of schizophrenia is estimated to be 0.5–1.5% (American Psychiatric Association 2000).

The onset of schizophrenia may be acute, but more often an insidious prodrome develops before the first psychotic episode (Keith and Matthews 1994, Klosterkotter et al. 2001). The usual prodrome consists of the gradual onset of social withdrawal, loss of interest in school or work, poor personal hygiene, and unusual behavior. Occasionally, there are psychotic symptoms present from childhood (Poulton et al. 2000) or other psychiatric disorders during adolescence (Weiser et al. 2001). As mentioned earlier, cluster A personality disorders may be evident before the onset of schizophrenia. Obstetrical and other perinatal complications have been implicated in the development of schizophrenia (Dalman et al. 1999, Jones et al. 1998).

The symptoms of the acute phase of schizophrenia consist of delusions; hallucinations; disorganized speech; grossly disorganized or catatonic behavior; and/or negative symptoms such as affective flattening, alogia, or avolition. Schizophrenia inevitably has a significant negative impact on functioning in work, social relations, and self-care. In the first 6 months of a schizophrenia-like illness, the disorder is called schizophreniform disorder. About one-third of patients receiving this diagnosis recover fully; the other two-thirds eventually progress to schizophrenia or schizoaffective illnesses (Beiser et al. 1988). Good prognostic signs in schizophreniform disorder are an acute onset (i.e., without prodromal deterioration), good premorbid social and occupational functioning, confusion and perplexity as part of the acute psychotic episode, and absence of blunted or flat affect.

The long-term course of schizophrenia is variable, but few persons recover fully. Some may experience good control of positive symptoms with medications and have reasonably stable clinical courses. Others show progressive deterioration with increasing functional disability. Negative symptoms are more persistent than positive symptoms (Arndt et al. 1995). Factors associated with a better prognosis in schizophrenia include good premorbid adjustment, acute onset, later age at onset, insight, being female, precipitating events, associated mood disturbance, brief duration of active phase symptoms, consistent compliance with medications, good interepisode functioning, minimal residual symptoms, absence of structural brain abnormalities, normal neurological examination, a family history of mood disorder, and no family history of schizophrenia (Table 29–14). There is some controversy over whether or not early treatment with antipsychotic medications confers a better prognosis (Ho et al. 2000, Craig et al. 2000). The paranoid subtype of schizophrenia appears to be the least severe; the disorganized subtype is the most severe (Kendler et al. 1984, Fenton and McGlashan 1991). Relapse following recovery from an episode is common (Robinson et al. 1999). Comorbid substance-related disorders may complicate the course of schizophrenia.

Patients who have illness episodes that are characterized by major episodes of mood disturbance, either depressed or manic, accompanied by schizophrenia-like psychotic symptoms and whose delusions and hallucinations are also present when mood symptoms are not, are said to have schizoaffective disorder. The prognosis for schizoaffective disorder, in general, and especially the bipolar type, is better.
than that for schizophrenia, as might be expected given the factors described as good prognostic signs in schizophrenia (Kendler 1987, 1994). Compared with schizophrenia, schizoaffective disorder occurs more frequently in women (American Psychiatric Association 2000).

The vast majority of disorders with typical onset in early adult life persist or recur in middle adult life. Some of these disorders may also have their initial onset after the age of 30 years. Table 29–15 summarizes the estimated prevalence and sex distribution of mental disorders of early adulthood.

**Problems of Middle Adult Life**

**Middle Adult Development**

Middle adult life may be applied to ages 30-65 years, which are characterized developmentally by consolidation and generativity in career and family life. Although potentially the most productive years of life, they are also fraught with obstacles and frustrations in the achievement of personal goals. Common stressors include marriage and divorce, parenting, career setbacks, recognition of unattainable goals, and death of parents. Any of these may serve as the focus of a midlife crisis.

**Types of Problems**

Psychosocial stressors may precipitate episodes of already existing disorders of virtually any type or initiate disorders de novo. Relatively few disorders have a typical onset between 30 and 65 years (Table 29-16). They include particular anxiety, psychotic, sleep, and substance-related disorders, and disorders associated with general medical conditions.

**Anxiety Disorders**

Although panic disorder most frequently presents in late adolescence, there is a second peak in age at onset distribution in the middle 30s (Fyer et al. 1995). Onset after the age of 45 years is unusual. The lifetime and 1-year prevalences of panic disorder thus peak between the ages of 30 and 44 years (Eaton et al. 1991). Panic attacks with intense fear and discomfort and accompanying symptoms are more likely to be spontaneous and unexpected early in the course of panic disorder. With long standing, chronic panic disorder, the recurrence of attacks tends to become associated with various situations that predispose to or precipitate them. Thus, in an effort to avoid situations from which escape might be difficult or help unavailable, a patient with recurrent panic attacks may develop agoraphobia.

**Psychotic Disorders**

A psychotic disorder with onset from middle-to-late adult life is delusional disorder (Kendler 1982). Delusional disorder differs symptomatically from the schizophrenia-related conditions discussed previously in having delusions involving situations that can occur in real life (nonbizarre), such as being followed, poisoned, infected, loved at a distance, or deceived by a spouse or lover, or having a disease. Behavior is not obviously odd or bizarre. Patients with delusional disorder are likely to have premorbid personalities that are extroverted, dominant, and hypersensitive, in contrast to patients with schizophrenia, whose premorbid personalities are typically introverted, submissive, and schizoid (Kendler 1980). In addition, delusional disorder usually has a much less severe impact on overall psychosocial functioning. Delusional disorder, in general, is equally common among men and women, although the jealous subtype may be more common among men. It is a rare disorder, affecting only about three persons in 10,000 (American Psychiatric Association 2000). The course of delusional disorder is quite variable. It may remit without relapse, have full periods of remission with subsequent relapses, or become chronic. Delusional disorders may develop in the context of obsessive-compulsive or body dysmorphic disorders, if the affected person becomes unable to recognize that her or his belief (obsession) or preoccupation is excessive or unreasonable; that is, she or he loses the ability to test reality.

**Sleep Disorders**

Breathing-related sleep disorders most frequently lead to clinical evaluation in persons between 40 and 60 years of age. Excessive sleepiness or insomnia is caused by obstructive or central sleep apnea syndrome or central alveolar hypventilation syndrome. Obstructive sleep apnea is more common in men than in women; women may develop the syndrome after menopause, however. The prevalence of obstructive sleep apnea is estimated as 1–10% and is even higher in the elderly (American Psychiatric Association 2000). Technically, these disorders are neurological or respiratory in nature but are encountered by psychiatrists evaluating patients with problems related to sleeping (Thorpy 1994). Central sleep apnea is common among elderly persons with CNS or cardiac disease. The course of breath-related sleep disorders is chronic.

**Substance-Related Disorders**

Because the peak onset of alcohol dependence is in the 20s to middle 30s, some alcohol-related disorders, which tend to develop in the context of dependency, may not become

‡Peak in age at onset in middle adult life.
NK, not known.
problems until middle adult life. These include episodes of alcohol withdrawal, amnestic syndrome, and dementia (Table 29–17). Alcohol-induced persisting amnestic disorder (Korsakoff’s syndrome) is a severe impairment in memory secondary to thiamine deficiency and is associated with prolonged heavy alcohol ingestion. Korsakoff’s syndrome usually develops after the age of 40 years and usually persists indefinitely, leading a person to require lifelong custodial care. Amnestic syndrome can also develop after prolonged and heavy use of sedatives, hypnotics, or anxiolytic drugs. Unlike the course of alcohol-induced disorder, the course of amnestic disorder associated with other sedative drugs is more variable and full recovery is possible. An amnestic syndrome can also develop after treatment with anticonvulsants or with exposure to environmental toxins, such as lead, mercury, insecticides, or industrial solvents. Full syndromes of dementia may also develop and persist after chronic alcohol ingestion or from other drugs or toxins.

**General Medical Conditions**
Because medical conditions have increased incidence during adult life, psychopathological conditions resulting from the direct physiological effects of general medical conditions are on the rise. General medical conditions (and their treatments) can cause delirium, dementia, amnestic disorder, psychotic disorder, mood disorder, anxiety disorder, catatonic disorder, sexual dysfunction, sleep disorder, and personality disorder. A general medical condition is likely to be the cause of a psychiatric syndrome under the following circumstances (American Psychiatric Association 2000):

1. A temporal relationship can be observed between the onset, exacerbation, or remission of the general medical condition and that of the mental disorder.
2. There are features of the psychiatric disturbance that are atypical of the primary mental disorder. Included would be an atypical age at onset, unusual symptoms, or symptoms that are disproportionately severe given the overall clinical picture.
3. There is an association established in the medical literature between the general medical condition and the psychiatric syndrome.

4. Previous episodes or a family history of the primary mental disorder is absent.

The actual age at highest risk, the sex distribution, and the clinical course of these disturbances are determined by the underlying medical condition. Neurological, endocrine, neoplastic, cardiovascular, infectious, and miscellaneous other medical illnesses have been implicated in the etiology of secondary mental disorders (Popkin and Tucker 1994). Medical conditions can also act as psychosocial stressors (Popkin et al. 1987), in which case the prognosis also depends on the management of the stress and the treatment of the mental disorder.

Pain is a common problem among adults. Estimates are that from 10% to 15% of adults in the US have some work impairment in any given year caused by back pain alone (American Psychiatric Association 2000). Pain may be associated with a general medical condition only, in which case it is not considered a mental disorder. When psychological factors are judged to play an important role in the onset, severity, exacerbation, or maintenance of pain, then a mental disorder is present, whether or not a medical condition also plays a role. Most pain syndromes that present to mental health professionals are chronic. Women appear to have a greater risk for at least certain chronic pain conditions, such as headaches and musculoskeletal pain. Pain disorder is often associated with mood and anxiety disorders.

The estimated prevalence and sex distribution of the few mental disorders with a peak in age at onset in middle adult life are included in Table 29–15.

**Problems of Late Life**

**Late Life Development**
The developmental demands of late life are many. Coping with physical illness, disability, or a diminished capacity for physical activity; adapting to retirement or reduced productivity at work; and dealing with grief after the loss of friends or a spouse are all frequent and challenging tasks. Maintaining emotional equilibrium by finding a new balance between desirable and undesirable events and circumstances (Baltes 1987) is a major undertaking.

**Types of Problems**
Risk for mood disturbances in late life remains high. Other emotional problems, substance abuse, and problems in physical functioning and in reality testing may occur. However peak age of risk is mainly for memory impairment associated with the dementias (Gurland 1996) (Table 29–18).

Memory Impairment

Dementia is characterized by multiple cognitive deficits, invariably including memory impairment but also such deficits as aphasia, apraxia, agnosia, and disturbance in executive functioning (e.g., planning, organization, abstraction). Dementia represents a decline in cognitive abilities that interferes with successful adaptive functioning. The decline in memory and intellectual functioning of dementia must be distinguished from analogous declines that occur with normal aging processes (Crook et al. 1986, Blackford and LaRue 1989). In addition to significant memory loss (Palmer et al. 2002), executive, decision-making dysfunction may herald the eventual development of Alzheimer’s disease (AD) (Chen et al. 2001). The cause of dementia (Table 29–19) may be degenerative CNS conditions such as Alzheimer’s or Parkinson’s disease; nondegenerative CNS conditions such as cerebrovascular disease, Huntington’s disease, subdural hematoma, normal-pressure hydrocephalus, viral and prion encephalitides, or brain tumor; or systemic illnesses such as anemia, renal or hepatic failure, hypothyroidism, vitamin B12 or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, or human immunodeficiency virus infection (Miller and Gustavson 2000, Reichman 2000). Chronic use or exposure to substances, including alcohol and environmental toxins, may also cause dementia. States of delirium related to the side effects of medications, acute infections, and other conditions may be mistaken for dementias.

Not all of the potential causes of dementia are increased in prevalence in late life. The most common types, however, such as the Alzheimer’s type and vascular type, usually present after the age of 65 years and progressively increase in frequency with increasing age. From 2% to 4% of the population older than 65 years are estimated to have Alzheimer’s dementia. In most ethnic groups, the majority of dementias are due to AD; vascular dementia is less common (Livingston et al. 1990b, Folstein et al. 1991). After the age of 85 years, 20% or more of the population is estimated to have a dementia. Women may be slightly more likely to develop AD than men. Men are more likely to develop vascular dementia (Folstein et al. 1991). Other causes of dementia in the elderly are much less common (Fratiglioni et al. 1991).

The course of dementia may be progressive, static, or remitting, depending on the underlying cause and the availability of effective treatment. The course of AD is slowly progressive, with an insidious onset, gradual loss of cognitive functions, and eventual neurological impairment (Cummings and Benson 1992). Behavioral disturbance, particularly agitation, is persistent in patients with AD (Devanand et al. 1997, Levy et al. 1996). The average duration from symptom onset to death is 8–10 years. Vascular or multi-infarct dementia has a more abrupt onset and a stepwise and fluctuating course corresponding to the events of cerebrovascular disease (Loeb and Gandolfo 1983, Small 1985).

Major and minor depression may be comorbid with Alzheimer’s dementia in over 50% of cases (Starkstein et al. 2005). Both major and minor depressions are associated with more severe psychopathology, functional impairment, and social dysfunction. Depressive symptoms in the elderly may be associated with subsequent cognitive decline (Yaaffe et al. 1999, Bassuk et al. 1998, Chodosh et al. 2007) and may increase the risk for developing AD (Devanand et al. 1996, Ownby et al. 2006) or be an early manifestation of the disease (Chen et al. 1999, Ganguli et al. 2006). Psychosis occurs in over 40% of patients with AD and may be associated with more rapid cognitive decline (Ropacki and Jeste 2005).

Mild cognitive impairment (MCI) in the elderly may predict subsequent conversion to AD in individuals with multiple cognitive impairments, not only memory deficits (Talbert et al. 2006). The presence of the risk factor gene apolipoprotein E epsilon4 allele appears to accelerate the onset of AD (Khachaturian et al. 2004) and the rate of brain atrophy (Chen et al. 2007). Heritability of AD is high for both men and women, nongenetic risk factors also play a role and may be a focus for interventions to decrease risk or delay onset (Gatz et al. 2006). AD brain pathology is more likely to be clinically expressed as dementia in women than in men (Barnes et al. 2005).

The elderly are also at highest risk for developing deliria. Delirium is a disturbance of consciousness, with reduced ability to focus, sustain, or shift attention. There are changes in cognitive functioning, such as memory impairment or disorientation; the development of perceptual disturbances, such as illusions and hallucinations; and agitation. The symptoms develop rapidly and tend to fluctuate during the course of the day.

There are many causes for delirium. General medical conditions include systemic infections, metabolic disorders, fluid and electrolyte imbalances, hepatic or renal disease, thiamine deficiency, postoperative states, hypertensive encephalopathy, postictal states, and head trauma. Many
substances, including prescribed medications, may also produce delirium. The elderly are particularly susceptible to developing delirium because many of the medical conditions mentioned have an increased prevalence in this age group and the CNS vulnerability of the population is increased. In the age group older than 65 years, 10–15% of those hospitalized have a delirium on admission and another 10–40% develop a delirium while hospitalized (American Psychiatric Association 2000). The in-hospital fatality rate for elderly delirious patients is 10–65% (Tune 2000). Because more women survive to an advanced age, more cases of delirium are encountered among women; however, male gender may be a risk factor for delirium in the elderly (American Psychiatric Association 2000).

**Emotional Problems**

Problems with depressed mood are common among the elderly. Although the prevalence of major depressive disorder is only about 1–2% (Blazer et al. 1987, Weissman et al. 1991), other depressive disorders including dysthymic disorder and atypical depression raise the rates to between 2% and 4%, and when subthreshold but clinically significant depressive symptoms are included, the rates rise to between 10% and 15% or higher (Livingston et al. 1990a Blazer and Williams 1980, Gurland et al. 1983). Women continue to be at greater risk for depression during late life (Dewey et al. 1993). One form of the so-called minor depression, that is, depression that is not stress-related and whose symptoms are below the threshold for major depression, has been found to be unique among persons older than the age of 60 years (Blazer et al. 1989): depressive complaints coupled with cognitive impairment. In addition, wide swings in mood (emotional lability) and sudden expressions of strong emotions (emotional incontinence) can occur in elderly patients with brain lesions.

Depressive symptoms and depressive disorders are common in people with physical illnesses and physical disability (Gurland et al. 1988, Turner and Noh 1988, Wells et al. 1993) but tend to improve as physical status improves (von Korff et al. 1990). Depression may increase the severity, awareness, and reporting of the symptoms of physical illness (Barsky et al. 1988). A majority of people older than the age of 65 years have at least one chronic physical disorder (Verbrugge 1990), so it is not surprising that comorbidity between depressive disorders and physical illnesses is substantial among the elderly or that risk for depression at an earlier stage in life, a few persons may experience the first onset in late life. Agoraphobia may develop in late life, precipitated by physical illness or a traumatic incident (Lindesay 1991). Anxiety disorders, as well as mood disorders, may be secondary to general medical conditions, such as cardiovascular, pulmonary, and neurological diseases. Use of prescription medications and withdrawal from alcohol or sedative, hypnotic, or anxiolytic drugs may also cause anxiety symptoms.

**Substance Abuse**

Contrary to common clinical opinion, substance abuse late in life may affect a significant minority of elderly persons. Increasing biological sensitivity to most psychoactive drugs, aggravation of common comorbid medical conditions by substances, and the occurrence of drug interactions between psychoactive substances and prescribed medications all make excessive substance use a likely clinical problem for the elderly (Atkinson 2000). Elderly patients with substance

The elderly are at risk for suicide (Pierce 1987, Hawton and Fagg 1990), particularly after the first onset of a major depressive disorder late in life (Pierce 1987, Conwell et al. 1991), after a psychosocial stressor such as divorce or bereavement (Livingston et al. 1990a), or in the context of alcoholism (Hawton and Fagg 1990) or a serious physical illness (Conwell et al. 1990). With advancing age, the frequency of attempted suicide decreases but the frequency of completed suicide increases.

Depression-induced cognitive impairment, also known as depressive dementia or pseudodementia, is a particular problem among the elderly (Stoudemire et al. 1989, Rabins and Pearlson 1994). Patients with pseudodementia cannot recall material presented to them to remember but can recognize familiar material, whereas patients with irreversible dementias are impaired in both free recall and recognition memory. MCI, detectable by neuropsychological testing, and complaints of difficulty with memory occur in many cases of “pure” depressive disorder in elders. In approximately 10% of depressive disorders in elders (15% of cases referred to clinics for memory disorders), a more prominent dementia-like syndrome presents. Depressive symptoms usually respond to treatment with concomitant improvement in cognitive impairment. However, most patients with more severe depressive pseudodementia eventually develop a true dementia in subsequent years (Kral 1983, Kral and Emery 1989).

The course of major depression in the elderly may be characterized by a more insidious onset than younger age groups (Berger et al. 1998) and higher relapse rates than in middle age (Mitchell and Subramaniam 2005), but overall outcome may not be worse (Alexopoulos et al. 1996). Concomitant physical illness, disability, cognitive impairment, and more severe depression (Cole et al. 1999), as well as onset late in life (Alexopoulos et al. 1996) and psychosis (Flint and Rifat 1998) have been shown to be associated with worse outcomes.

Problems with anxiety are common among the elderly, affecting up to 20% of the population older than the age of 65 years at any given time (Blazer et al. 1991). Specific phobias are the most common disturbance, with an estimated 1-month prevalence rate of 4.8% (Eaton et al. 1991). Although most anxiety disorders in the elderly have an onset at an earlier stage in life, a few persons may experience the first onset in late life. Agoraphobia may develop in late life, precipitated by physical illness or a traumatic incident (Lindesay 1991). Anxiety disorders, as well as mood disorders, may be secondary to general medical conditions, such as cardiovascular, pulmonary, and neurological diseases. Use of prescription medications and withdrawal from alcohol or sedative, hypnotic, or anxiolytic drugs may also cause anxiety symptoms.
use disorders may present with uncontrolled medical illnesses; with secondary substance-related disorders such as amnestic syndrome, delirium, or dementia; or with general and nonspecific signs and symptoms of deterioration, such as poor personal hygiene, malnutrition, muscle weakness, gait disturbances, frequent falls or other injuries, or mood or behavior changes.

Alcohol problems are the most common substance use problems among the elderly, with a prevalence of 4–20% depending on the clinical setting in which the patients are seen (Atkinson 2000, Liberto et al. 1992). Estimates are about 1% in the general population (Grant 1997). Although alcohol abuse tends to decline with advancing age, in part because of premature deaths among early-onset alcohol abusers, up to one-half or more of elders with problem drinking have onset in middle or late life (Atkinson 1990). These disorders may be precipitated by age-specific stressors such as retirement or loss of significant others through death. The course and outcome of late-onset alcoholism may be better than for early-onset alcoholism, with milder symptoms and more frequent spontaneous remission (Atkinson 1994, Moos et al. 1991). Rates of alcoholism after 85 years are negligible.

Another common substance-related problem among the elderly is dependence on sedative, hypnotic, or anxiolytic drugs. These drugs are most often prescribed to elderly patients for insomnia or anxiety and are taken sometimes for many years, with physical dependence resulting. Benzodiazepines are associated with excessive daytime sedation, ataxia, and cognitive impairment, and cessation of treatment may result in recurrence, rebound, or frank withdrawal symptoms.

Disturbances in Physical Functioning
Sleep disorders and problems with pain are among the most common disturbances in physical functioning in the elderly. Sleep disturbances have been found to affect 12–15% of the population older than 65 years (Ford and Kamerow 1989). Sleep disturbances in the elderly may be a consequence of depression or a risk factor for developing depression. Psychosocial stressors, medical illness, and increasing physical limitations in general all contribute to the disturbances of sleep and mood in the elderly. The course of sleep disturbance in the elderly often depends on the identification of an underlying condition and its successful treatment.

Medical and psychiatric illnesses make pain a special problem among the elderly. Psychosocial stressors may interfere with a patient’s ability to cope with the pain of a medical condition. Twenty five to 50% of community-dwelling elderly suffer from pain. Acute pain in the elderly most commonly results from surgery or injury or from musculoskeletal conditions, such as arthritis (Clark 2000). Mental disorders in the elderly that can present with pain as a major complaint include major depressive disorder, dysthymic disorder, panic disorder, and any of the somatoform disorders.

Reality Testing
Late-onset schizophrenia or paraphrenia is a psychotic illness with a first onset after the age of 65 years. Seven percent of hospitalized patients with schizophrenia appear to have had an onset after the age of 60 years and 3% after the age of 70 years (Harris and Jeste 1988). In paraphrenia, distinctive psychopathological features include more frequent persecutory delusions and auditory hallucinations and less frequent formal thought disorder and negative symptoms. A common way in which the circumstances of the elderly may shape the expression of a delusion is the so-called partition delusion that some strangers, substance, or force enters the patient’s home through the walls. This phenomenon is thought to be related to the social isolation and homebound existence common in the elderly (Pearlson and Petty 1994). The premorbid personalities of persons developing schizophrenia late in life are schizoid or paranoid. Occupational adjustment, however, has usually been adequate until middle adult life (McGlashan 1994). Once the condition develops, the course is chronic with a poor prognosis. Paraphrenia is significantly more common in women than in men.

Other conditions that may cause psychotic syndromes in the elderly are early-onset schizophrenia, delusional disorder, mood disorders with psychotic features, Alzheimer’s and vascular dementias, and other medical conditions, substances, and prescribed medications.

Table 29–20 summarizes the estimated prevalence and sex ratio of selected mental disorders of late life.

Conclusion
Psychopathology occurs throughout the life span, from infancy to death. Certain forms of psychopathology are limited to specific stages in life, but most have an onset in childhood or adolescence and can be observed at any stage. Particular disorders have a peak age at onset during specific intervals of the life span. Some seem related to the developmental themes of the stage in which they tend to develop. The manifestations of psychopathology may change in expression in relationship to age. Men and women differ in their susceptibilities to certain disorders, the age at which they are at greatest risk, certain symptom patterns, and, in some cases, in their prognoses.

Given the wide range of psychopathology encountered across the life span, clinicians must cast a wide net in collecting diagnostically relevant information. They must exert good clinical judgment in interpreting the information collected, including a judicious weighing of the evidence supporting diagnostic criteria. They must view patients through the filter of their cultural context. And they must apply accepted diagnostic algorithms to reach the most accurate diagnosis for each patient’s problem. The remaining chapters in this section are meant to assist in these endeavors.

Every psychiatric evaluation must be specific to the context in which it occurs. The evaluation of a patient in the psychiatric emergency room is different from the evaluation of a graduate student applying for psychoanalysis, a member of a couple who seeks consultation for marital distress, or an indicted prisoner who is being evaluated for competence to stand trial. In each case, the evaluation and treatment plan are tailored to the situation.

In this chapter, we present an outline of the most thorough approach to psychiatric evaluation—that is, the one most typically followed when someone is admitted to a psychiatric inpatient unit. The complete psychiatric evaluation consists of the psychiatric interview; physical examination, including neurological assessment; laboratory testing; and, as appropriate, neuropsychological testing, structured interviews, and brain imaging. The results of the evaluation are then used to assess risk, reach tentative, and, if possible, definitive diagnoses, and complete initial and comprehensive treatment plans. Clearly, the length, detail, and order of the evaluation need to be modified when it is conducted in different settings. The clinician needs to assess the goals of the interview, the patient’s tolerance for questioning, and the time available. Table 30–1 shows the variation of the psychiatric evaluation with the type of setting.

**Psychiatric Interview**

Despite the advent of brain imaging tests, standardized diagnostic criteria, and structured rating scales, the psychiatric interview (Table 30–2) remains the cornerstone of clinical evaluation in psychiatry. Whether it is conducted in a busy psychiatric emergency room, an inpatient ward, or an out-patient office, the psychiatric interview is essential for establishing rapport with the patient, initiating the therapeutic alliance, eliciting the psychiatric history, and performing the Mental Status Examination (MSE). When conducted skillfully, the interview may appear to be a relaxed and casual conversation, but it is actually an extremely precise diagnostic tool composed of specific elements: the identifying information, the chief complaint, the history of present illness, the past psychiatric history, the personal history, the family history, the medical history, the substance use history, and the MSE. The essential features of the psychiatric interview are highlighted here. For a more complete discussion of the psychiatric interview, see Chapter 3 (The Psychiatric Interview).

Before beginning the interview, the psychiatrist should introduce himself or herself, explain the purpose of the interview, and try to make the patient as comfortable as possible. The interview gives the most accurate information when the psychiatrist and the patient speak in a language in which they are both fluent. When this is not possible, a translator should be used, preferably one with mental health training or experience. Even then, some of the subtleties of the patient’s communication are lost.

**Identifying Information**

Most interviewers find it helpful to begin with a few questions designed to identify the patient in a general way. Asking the patient’s name, age, address, marital status, and occupation provides a quick general picture and begins the interview with emotionally neutral material. If the interviewer chooses to begin in this way, it is important to complete this section rapidly and then give the patient a chance to respond to open-ended questions. This allows the interviewer to get a more accurate sense of the patient’s spontaneous speech patterns, thought processes, and thought content. If the patient becomes too disorganized in response to this change, the

The psychiatrist can revert to more focused questions to structure and organize the interview. If it is possible, within the context of the interview, other pieces of identifying information, such as the patient’s ethnic group and religious affiliation, should be obtained.

Chief Complaint

At the start, the interviewer wants to ascertain exactly why the patient is seeking psychiatric help at this time, or, if the patient is not requesting help, the patient’s understanding of the purpose of the evaluation. The interviewer may begin with a fairly general question, such as “What brings you to the hospital at this time?” The patient may have a long history of psychiatric illness, but the chief complaint refers only to the acute problem that necessitates the current intervention. The interviewer should try to help the patient distinguish the chief complaint from any chronic problems, as in the following example:

**Interviewer:** Can you tell me what brings you to see a psychiatrist at this time?

**Patient:** Well, I have had schizophrenia for 25 years.

**Interviewer:** I see. But my guess is that something happened recently that has prompted you to come in today, rather than several months ago.

**Patient:** Oh, yes. Yesterday my wife kicked me out of the house. I’m homeless.

Here, the patient’s chief complaint is homelessness; the schizophrenia is part of his psychiatric history. Although a psychotic patient may offer a chief complaint that seems incoherent or unrealistic, it is important to collect the chief complaint in the patient’s words and later look to other sources of information for additional history. Similarly, in response to the question, “What brings you to seek psychotherapy at this time?” a patient may begin to answer by detailing his or her childhood, but the interviewer should help the patient to focus on current issues that precipitated the consultation. Some patients may not be able to cite a chief complaint: “My wife sent me” or “There’s no problem. I don’t know why the police picked me up.” Even these answers give the interviewer information about the patient’s current situation, which can be elaborated on by asking the patient for more details.

It is important to remember that while a clinician may form his or her own ideas about the patient’s problems, understanding what the patient feels he or she needs help with is critical, both for forming an alliance with the patient and because most patients ultimately engage and follow up in treatment to address what they feel is troubling them (as opposed to what the clinician or others believe they need).

When the interview is being conducted for a third party—for example, to determine whether a patient is eligible...
History of Present Illness
Having obtained the chief complaint, the interviewer should clarify the nature of the present illness. By definition, the present illness begins with the onset of signs and symptoms that characterize the current episode of illness. For example, the present illness of a manic patient with chronic bipolar disorder, who was asymptomatic for the past 3 years, would begin with the onset of the current episode of mania. The interviewer should determine the duration of the present illness, as well as precipitating factors such as psychosocial stressors, substance use, discontinuing medication, and medical illnesses. The patient should be allowed to tell the story, and the clinician should follow up with specific diagnostic questions. For example, a patient who tells a story of 6 months of sadness after the death of a relative should then be asked about vegetative symptoms of depression, suicidal ideation, and guilty ruminations. Particular attention should be paid to behaviors or statements that would indicate that the patient may be at an increased risk of hurting himself or causing harm to another person.

Past Psychiatric History
The interviewer should ask for information regarding any previous episodes of psychiatric illness or treatment, including hospitalization, medication, outpatient therapy, substance use treatment, use of complimentary treatments (e.g., herbal, acupuncture), self-help groups, and consultation with culture-specific healers such as shamans. The duration and effectiveness of treatment should be ascertained, as well as the patient’s general experience of her or his psychiatric treatment to date. Again, significant suicidal or violent ideation or behavior are relevant parts of a patient’s past psychiatric history.

Personal History
No interview is complete without some understanding of the patient’s background and life circumstances (Table 30–3). Within the constraints of the interviewer’s time and the patient’s tolerance for further questioning, the clinician should inquire about the patient’s upbringing, educational and vocational history, interpersonal relations, and current social situation. It is important to inquire about the patient’s sexual history and to ask about the risk factors for human immunodeficiency virus (HIV) infection, such as a history of multiple partners, unprotected vaginal and anal intercourse, and intravenous drug use. This information is important not only for the assessment and diagnosis of the present illness but also for treatment planning. The relevance of the information outlined in Table 30–3 depends on the purpose of the evaluation and the age of the patient, and some of the information may only be available from third party informants (e.g., parents of a patient).

Family History
The interviewer should ask the patient specifically about any relatives with a history of psychiatric illness or treatment, suicide, or substance use. This information may be of diagnostic importance. For example, a patient who presents with a first episode of acute psychosis may have any one of a number of disorders, but a family history of affective disorders may lead the interviewer to suspect a diagnosis of bipolar disorder or major depression with psychotic features rather than schizophrenia. This information is also important for treatment planning, particularly if the patient’s primary caregivers are also psychiatrically ill or also abuse substances. Similarly, family history is relevant for certain behaviors, such as suicide, where a positive family history may place the patient at an increased risk for the same behavior.

Medical History
A careful review of a patient’s medical history is an important part of the psychiatric interview because medical conditions can dramatically affect psychiatric status. Many medical disorders such as endocrinological conditions (thyroid disease, pheochromocytomas, pituitary adenomas), neurological disorders (Parkinson’s disease, central nervous system neoplasms, Wilson’s disease, stroke

syndromes, head trauma), and infectious diseases (HIV infection, meningitis, sepsis) can have manifestations that include psychiatric symptoms (see Chapter 52). When such a disorder is suspected, a rigorous inquiry is essential. A review of all of the patient’s medications, including over-the-counter preparations and alternative remedies, is important because many of these substances can produce or exacerbate psychiatric symptoms. For example, propranolol taken for hypertension may produce symptoms of depression, and scopolamine taken for motion sickness may induce delirium. Moreover, the toll of chronic, debilitating medical conditions or the acute onset of a catastrophic, physical illness may be accompanied by secondary psychiatric symptoms that can be fully understood only in the context of the patient’s medical condition.

In addition, the medical history is a prerequisite for beginning psychotropic medication or other somatic treatments as it allows the psychiatrist to weigh potential toxicities, side effects, and drug interactions based on the patient’s physical vulnerabilities and concurrent medications.

**Substance Use History**

The interviewer should inquire about which substances are used, under what circumstances, and the quantity, variety, and duration of use (Table 30–4). A question such as “Do you drink alcohol?” is likely to be answered with a quick “No.” A better question, such as “How much alcohol do you drink?” communicates to the patient that the clinician is not making a value judgment and is more likely to elicit an accurate answer. Similarly, asking about each substance separately as opposed to a blanket question such as “Have you ever used illegal drugs?” is more likely to result in a positive response. The interviewer must be sure to ask about past and current drug injection, including the sharing of injection equipment, to assess for HIV risk factors (Table 30–5).

**Mental Status Examination**

The MSE is a structured way to assess a patient’s mental state at a given time. Unlike the parts of the interview that focus on the history, the MSE provides a descriptive snapshot of the patient at the interview. Much of the information needed for the evaluation of appearance, behavior, and speech is gathered without specific questioning during the course of the interview. However, the interviewer generally wants to ask specific questions to assess the patient’s mood, thought process and content, and cognitive functioning. Bearing in mind the outline of the MSE (Table 30–6) ensures that the interview is comprehensive. The components of the MSE are described in the following paragraphs.

- **Appearance.** The interviewer should note the patient’s general appearance, including grooming, level of hygiene, and attire.

- **Behavior.** This includes the patient’s level of cooperativeness with the interview, motor excitement or retardation, abnormal movements (e.g., tardive dyskinesia, tremors), and maintenance of eye contact with the interviewer.

- **Speech.** The psychiatrist should carefully assess the patient’s speech for rate, fluency, clarity, and volume. The interviewer may want to question the patient directly about his or her speech. For example, the psychiatrist can gain valuable diagnostic information by asking

A patient with pressured speech if she or he is able to modulate the rate of the speech or by asking whether a dysarthric patient is aware of not speaking clearly. A bipolar patient who is in the midst of a manic episode is not able to slow down her or his speech; a fast-talking anxious person is able to do so. Similarly, a patient whose dysarthria is secondary to ill-fitting dentures is aware of this problem whereas an intoxicated person is not. It is helpful to clarify whether patients with a speech abnormality feel that this is their normal speech pattern or a new problem.

- **Mood and Affect.** The interviewer should be aware of the patient’s mood and affect. This may be evident from the way in which the patient answers other questions and tells the history, but specific questions are often indicated. The patient’s mood is a pervasive affective state, and it is often helpful to simply ask, “What has your mood been like lately?” or “How would you describe your mood?” In contrast, affect is the way in which one modulates and conveys the state of one’s feeling from moment to moment. The clinician judges the congruity between the material the patient is presenting and the accompanying affect; for example, an appropriate affect would be reflected by sadness when discussing the death of a loved one or happiness when describing a child’s accomplishments. The clinician is also interested in whether the patient is capable of displaying a broad range of affect or whether affect is more limited (e.g., a constricted affect in a depressed patient), as well as whether the affect is labile (shifts too rapidly).

- **Thought.** The clinician should assess the patient’s thought process and content. Thought process is the form of the patient’s thoughts—are they organized and goal directed or are they tangential, circumstantial, or loosely associated? (See Chapter 35 for definitions and examples.) If the patient’s thought processes are difficult to understand, the clinician can indicate his or her difficulty in following what is being said and then assess the patient’s response to this intervention. Some patients—such as patients with stroke who have nonfluent aphasias—may appear to have disorganized speech but are aware that they are not making sense, whereas those with fluent aphasias, psychosis, and delirium are not necessarily aware of their impairments. The psychiatrist should ask specifically about the patient’s thought content, including delusions (grandiose, persecutory, somatic), obsessions, phobias, and suicidal and violent (or even homicidal) ideation. The presence of delusional material is often obvious from unsolicited statements made by the patient, and in very delusional patients, the interviewer may have difficulty in getting the patient to focus on anything else because of the perceived importance of the delusional content to the patient. Although the above questions should be asked with tact and empathy, they should always be asked. For example, patients are generally relieved that the interviewer has broached the subject of suicide, and simply asking the question does not give patients ideas that they have not had before.

- **Perception.** Clinicians must inquire about hallucinations of all types, i.e., auditory, visual, tactile, olfactory, and gustatory. Auditory hallucinations are the most common type of hallucination, and it is important to assess whether the patient is actually experiencing voices as coming from the outside, as opposed to, for example, an individual “hearing” one’s own thoughts. It is less common for a psychotic patient to experience visual hallucinations as a result of a psychotic illness alone, and such cases should prompt a work up for other medical or neurological conditions. Hallucinations must also be distinguished from illusions, which are misperceptions of actual external stimuli. While patients may deny hallucinations, an interviewer should note in his MSE whether a patient nevertheless appears to be responding to internal stimuli.

- **Cognition.** Every psychiatric interview should include some assessment of the patient’s cognitive functioning (see also Chapter 32 [Neuropsychological Testing]). This includes the patient’s level of awareness, alertness, and orientation (to person, place, and time). If there is a question about the patient’s memory, formal memory testing may be done to assess short-term, intermediate, and long-term memory. A patient who can answer questions for 30 min is clearly attentive, but any doubts about the patient’s attentiveness should prompt a formal assessment—for example, asking the patient to recite a series of digits forward and backward. Before assessing the patient’s calculations and fund of knowledge, it is
important to ascertain the patient’s level of education. Formal assessment of the patient’s ability to abstract may be unnecessary for a patient who has used abstract constructions throughout the interview, but the interviewer may want to ask formally for interpretations of similes and proverbs. It is often helpful to begin with simple constructions—for example, asking the patient the meaning of such phrases as “He has a warm heart” or “Save your money for a rainy day.” Patients whose native language is not English may have difficulty in this area that does not reflect a lack of ability to abstract.

The interviewer should gain a full understanding of the patient’s insight into the illness by asking why, in the patient’s opinion, he/she is currently in need of psychiatric care and what has caused the problems the patient is experiencing. Finally, the interviewer should learn about the patient’s judgment. This is best assessed in terms of the circumstances of the patient’s life—for example, asking a mother how she would deal with a situation in which she had to leave her children to go to the store, or asking a chronically ill person what he does when he sees that he is running out of medicine.

The interviewer may want to use the Mini-MSE to quantify the degree of cognitive impairment of a patient with obvious cognitive abnormalities. This can be useful as an initial diagnostic tool, as well as a means of assessing changes in cognitive function over time. The Mini-MSE is outlined in Figure 30–1. To the extent that a patient displays cognitive deficits that appear out of proportion to a tentative diagnosis, and depending on the parallel history obtained, more formal neuropsychiatric testing may be warranted.

### Physical Examination

The physical examination is an important part of the comprehensive psychiatric evaluation for several reasons. First, many patients who present with psychiatric symptoms may have underlying medical problems that are causing or exacerbating the presenting symptoms. For example, an agitated, delirious patient may be septic, or a patient being treated for an autoimmune disorder who develops new onset paranoia may have a steroid-induced psychosis. Second, the patient’s physical capacity to tolerate certain psychiatric medications, such as clozapine or lithium, must be assessed. Finally, many patients who present to a psychiatrist have had inadequate medical care and should be routinely examined to assess their general level of physical health. This is especially true for patients with chronic mental illness or substance abuse. In some settings, such as emergency rooms and inpatient wards, the psychiatrist may want to perform the physical examination; in others, it may be more appropriate to refer the patient to a general practitioner for this purpose.

Genital, rectal, and breast examinations can usually be included even for anxious and paranoid patients, but when they must be postponed, care should be taken to complete them at a later time. A same-sex chaperone is necessary for the security of both the patient and the examiner.

Certain aspects of the information obtained in the psychiatric interview should alert the psychiatrist to the need for a physical examination. Any indication (Table 30–7) from the history that the psychiatric symptoms followed physical trauma, infection, medical illness, or drug ingestion should prompt a full physical examination. Similarly, the acute

</tr>
</tbody>
</table>

onset of psychiatric symptoms in a previously psychiatrically healthy individual, as well as symptoms arising at an unusual age, should raise questions about potential medical causes (Table 30–8).

New-onset psychosis or mania in a previously healthy 65-year-old person is representative of a case requiring pursuit of a medical condition as the cause because these disorders do not commonly present at this age. Any gross physical abnormalities, such as gait disturbances, skin lesions, eye movement abnormalities, lacerations, flushed skin, or drooling, should raise the interviewer’s suspicion that there might be an underlying medical condition. Urinary or fecal incontinence is also highly suggestive of a medical etiology. Stigmas of drug or alcohol use or abuse, such as dilated or pinpoint pupils, track marks, evidence of skin popping, or frank evidence of intoxication (e.g., alcohol on the breath), should also signal the need for a more thorough physical examination. Abnormalities of speech, such as impaired fluency or dysarthria, may indicate the presence of an underlying medical disturbance. Many mood problems may be caused by physical disorders, and even apparently healthy patients with dysthymia may have hypothyroidism that can be treated medically. Finally, any cognitive disturbances, such as disorientation, fluctuating level of alertness, inattentiveness, or memory problems, are, until proved otherwise, evidence of a physical problem that is causing psychiatric symptoms. In such situations, careful attention should be paid to the patient’s vital signs, neurological examination

</table>
(see the Section titled Neurological Examination), and any indications of infection.

In a hospital setting, a physical examination, including a careful assessment of the patient’s vital signs (including orthostatic measurements), cardiovascular status, and pulmonary status, precedes the prescription of the most psychiatric medications. For example, newer antipsychotic medications should not be prescribed without taking into account a patient’s weight, and the presence of or risk for developing diabetes mellitus and dyslipidemias, given the side-effect profile of many of these medications. Psychiatrists should pay particular attention to a patient’s cardiovascular status (e.g., electrocardiographic abnormalities, orthostatic hypotension, decreased cardiac ejection fraction) before beginning tricyclic antidepressants, which may induce cardiac conduction disturbances and thus must be used with caution for patients with such cardiac abnormalities as arrhythmias or other conduction abnormalities. If beta-blockers such as propranolol are being considered, patients should be evaluated for the presence of asthma, which may be exacerbated by these drugs.

Physical examination may also be warranted during treatment with medication if physical symptoms arise. For example, fever and a change of mental status during a course of neuroleptics require a full physical and neurological examination to rule out neuroleptic malignant syndrome. Urinary retention induced by medications with anticholinergic side effects requires an abdominal examination to assess bladder fullness. Anticholinergic-induced constipation may warrant abdominal or rectal examination to assess for impaction. Increased blood glucose levels or significant weight gain may necessitate a reevaluation of the risks and benefits associated with one of the atypical antipsychotics. When patients are seen in office-based practices, the psychiatrist most often obtains a careful medical history and may complete simple procedures such as blood pressure and weight checks but will usually refer the patient to another physician for a complete physical examination.

**Neurological Examination**

In the hospital setting, every patient should have a thorough neurological examination. Patients who have a history of neurological disturbances, such as strokes, seizure disorders, central nervous system neoplasms, dementias, and movement disorders, should be carefully evaluated, perhaps by a neurologist. The neurological examination should rule out any lateralizing neurological signs which would point toward the presence of a focal lesion. Unilateral weakness or abnormalities in pupil size or eye movements might suggest a focal neoplasm, infection (such as toxoplasmosis), intracranial bleeding, or a stroke, which may explain such psychiatric symptoms as confusion, sudden onset of speech difficulties, psychosis, or even depression. Stiffness and cogwheel rigidity are classical signs of Parkinson’s disease, a disorder which may be associated with such psychiatric symptoms as depression, psychosis, and dementia.

Patients with acquired immunodeficiency syndrome should also be carefully evaluated neurologically because many neurological manifestations of advanced HIV-related illness (including HIV-associated dementia and central nervous system opportunistic infections) and the medicines administered to treat these illnesses may produce psychiatric symptoms, including depression, delirium, mania, and psychosis. Gait should be carefully examined in psychiatric patients because certain neurological conditions in which gait disturbances are prominent, such as normal-pressure hydrocephalus, tertiary syphilis (tabes dorsalis), and combined system disease (caused by vitamin B₁₂ deficiency) may produce a variety of psychiatric symptoms.

**Psychological and Neuropsychological Testing**

Psychological and neuropsychological tests are standard instruments used to measure specific aspects of mental functioning. They are usually administered by psychologists or other professionals who have been trained in their use and interpretation. In most cases, several tests, often referred to as a battery, are performed together. These test results must then be interpreted in the context of the broad clinical picture of the patient. The neuropsychological evaluation is discussed in detail in Chapter 32 (Neuropsychological Testing).

Because of the time and expense involved, testing is usually reserved for situations in which there is some uncertainty about a patient’s diagnosis, cognitive capacity, or psychological functioning. There are, however, times when psychological testing is essential—for example, IQ testing to establish the severity of mental retardation. In addition, giving simple tests of cognitive functioning, such as asking the patient to copy Bender Gestalt diagrams (Figure 30–2),

Table 30–11 gives an example of how these different rating scales approach the assessment of two symptoms: guilt, a purely subjective state of mind; and suicide risk, an inclination that is assessed using both subjective and behavioral components. It is important to keep in mind that these instruments are not a substitute for a more thorough assessment for risk of danger to self or others (see the Section titled Assessment of Risk).

**Structured Clinical Instruments and Rating Scales**

Structured instruments and rating scales have been developed primarily for research purposes. They allow investigators to compare the findings in different studies by ensuring that similar data and criteria have been used to establish diagnoses and to measure the presence and severity of psychiatric symptoms and their response to treatment. Many types of mental health professionals and, in some cases, nonclinicians can be trained to administer these rating scales.

Although many practicing clinicians do not commonly use structured instruments to assess or follow patients, a small number of rating scales have come to be used routinely in clinical practice. For example, the Abnormal Involuntary Movement Scale (Figure 30–3) is often used to monitor patients receiving antipsychotic medication for the presence of tardive dyskinesia, and the Global Assessment of Functioning Scale (Figure 30–4), which is a slight modification of the Global Assessment Scale, is now used in Axis V in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR). In other areas, such as suicide and violence risk assessment, clinical judgment supplemented by structured or semistructured instruments, is becoming more common place. Moreover, the use of standardized instruments in clinical practice may help ensure, among other things, a more comprehensive evaluation and improved tracking of symptomatology over time.

Table 30–10 shows some of the most commonly cited structured instruments and rating scales for adults. Hundreds of other specialized scales are also in use to assess such diverse areas as specific symptoms clusters, personality disorder, aggressive behavior, sexual practices, stressful life events, and quality of life.

**Laboratory Assessments**

A variety of laboratory tests can aid in the clinical evaluation of the psychiatric patient (Table 30–12).

**Serological Evaluations**

Blood tests are particularly helpful in ruling out medical causes of psychiatric symptoms.

**Toxicology**

When the clinician suspects that the ingestion of a substance has caused the presenting symptoms, a urine toxicology screen (Table 30–13) and blood alcohol level determination are indicated. (It is important to remember that alcohol is detectable in the blood for only a matter of hours and that a level of zero may indicate that the symptoms are due to a withdrawal syndrome, and thus does not rule out alcohol as an inciting factor.) Depending on the purpose and setting of the evaluation, testing for certain drugs may also be performed on blood, sweat, saliva, and hair. Although the technology is relatively new, hair in particular offers a means of detecting drug use over a longer retrospective time period than testing by other methods (i.e., up to several months). If the patient is known to be taking certain psychiatric medications, such as lithium, tricyclic antidepressants, and anticonvulsants, levels of these medications should be tested as toxic levels may cause a variety of psychiatric symptoms. A variety of other medications, substance of abuse, and toxins can alter mental status (see Table 30–21 for those that can present as medical emergencies) and testing for their presence may be necessary depending on the patient’s history and symptoms.

**Complete Blood Count**

The complete blood count is part of the general laboratory evaluation of a new patient. It is used to screen for multiple
problems, most commonly infections and anemia. In cases in which alcoholism is suspected or the mean corpuscular volume indicates a macrocytic anemia, vitamin B₁₂ and folate levels should be tested. Vitamin B₁₂ deficiency may lead to combined system disease, which can present with psychiatric symptoms such as irritability and forgetfulness in the early stages and dementia or frank psychosis in the later stages. The complete blood count is routinely used to monitor white blood cell counts in patients taking clozapine due to the risk of agranulocytosis. Additional emergency complete blood counts may be necessary if such a patient develops fever, malaise, or other symptoms of infection while on clozapine. Certain mood stabilizers, such as carbamazepine and divalproex sodium, can induce a variety of blood dyscrasias.

**Blood Glucose**

The blood glucose test is an inexpensive, essential test in the evaluation of patients with a new onset of central nervous system dysfunction, psychosis, affective disorders, and anxiety disorders. Hypoglycemia may produce lethargy and vegetative symptoms that may mimic those of depression, and hyperglycemia may produce anxiety and delirium. This test is clearly indicated for known diabetics who present with the first onset of psychiatric symptoms. Atypical antipsychotic medications, such as clozapine and olanzapine, can

elevate blood sugar, increasing the risk of a patient developing diabetes.

Kidney Function Tests
The blood urea nitrogen and creatinine levels are important measures of kidney function. Kidney function tests are used to screen for kidney failure and hypovolemic states (in which blood urea nitrogen and creatinine levels increase). Both of these states can cause mental status changes. It is also essential to perform these tests before beginning therapy with lithium, which is cleared by the kidneys.

Liver Function Tests
These tests, which check for levels of various enzymes in the liver and certain products made by the liver, are indicated when there is some suspicion that liver disease is present. They help the clinician to screen for hepatic encephalopathy, hepatitis, alcoholism, and biliary tract disease. They include creatine kinase, which is often elevated in neuroleptic malignant syndrome as well as in other conditions in which muscle rigidity is prominent. Monitoring of liver function tests is essential with some psychotropic medications such as divalproex sodium and nefazodone. Moreover, since many medications are metabolized by liver enzymes, potentially toxic levels can accumulate when liver disease is present. Medication doses may need to be adjusted and/or certain medications may even need to be discontinued when liver function is impaired.

Thyroid Function Tests
Both hypothyroidism and hyperthyroidism can mimic the symptoms of psychiatric disorders. Hyperthyroidism may mimic anxiety disorders, psychosis, or mania, and hypothyroidism may mimic dysthymia and depression. Thyroid function tests are therefore indicated in cases of new onset of a mental illness. In addition, thyroid function should always be tested when initiating lithium therapy and periodically thereafter because lithium may cause hypothyroidism.

Syphilis Screening
These tests should be done for any patient with new-onset psychosis. They have become particularly important with the increasing incidence of syphilitic infection associated with the HIV epidemic. Positive serologic results in the presence of unexplained psychiatric symptoms necessitate a lumbar puncture to test for neurosyphilis.

Blood Cultures
Blood cultures are indicated in the evaluation of medically ill patients who develop fever and psychiatric symptoms such as confusion, disorientation, and agitation because this delirium may be secondary to sepsis.

HIV Antibody Testing
The Center for Disease Control and Prevention (2006) now recommends routinely offering HIV antibody testing to all patients. In addition, psychiatric patients have elevated rates of HIV infection when compared to the general population due to the frequent presence of HIV-related risk behaviors. (see Table 30–5). HIV infection should always be suspected in cases of unexplained central nervous system dysfunction, and when psychiatric illness is accompanied by suggestive medical findings such as thrush or swollen

lymph nodes. Clinicians should be aware of state and local requirements regarding consent and counseling when HIV testing is performed. Regardless of these requirements, some patients may need additional education and/or support.

**Pregnancy Testing**

It is advisable to perform pregnancy testing (e.g., serologic test for the presence of human chorionic gonadotropin b-subunit) for all women of childbearing age before conducting imaging studies or initiating therapy with any psychotropic medication or other somatic treatment. Clinicians should be especially careful in this regard with respect to medications associated with fetal malformations such as anticonvulsants and benzodiazepines.

**Urine Testing**

Urine tests for pregnancy are often indicated in the emergency room setting in which an immediate result is required before the initiation of various imaging studies and/or drug therapy. Urinalysis also assists in diagnosing certain medical conditions that can alter mental status such as diabetic ketoacidosis and urinary tract infection with sepsis.

**Cerebrospinal Fluid Evaluation**

Lumbar puncture may be indicated to test for infections, including meningitis, neurosyphilis, toxoplasmosis, and tuberculosis of the central nervous system. It is indicated in the evaluation of patients with an acute change of mental status, who present with symptoms such as confusion, disorientation, or decreased or fluctuating alertness when accompanied by fever (Table 30–14). It is also an important part of the evaluation of patients who have new-onset seizures or who are suspected of having neuroleptic malignant syndrome because these symptoms may be caused by central nervous system infections. In cases in which increased cerebrospinal fluid pressure is suspected, lumbar puncture should be preceded by computed tomographic (CT) scanning to evaluate for mass lesions.

**Electrocardiogram**

Because it is important to screen for conduction disturbances and cardiac arrhythmias before beginning therapy with tricyclic antidepressants, an electrocardiogram should precede the initiation of therapy. An electrocardiogram is also indicated before beginning certain other psychotropic medications that may produce electrocardiographic changes (Tables 30–15 and 30–16). An electrocardiographic...
Comparison of Rating Scales for Assessing Guilt and Suicide Risk

<table>
<thead>
<tr>
<th>Rating Scale</th>
<th>Guilt</th>
<th>Suicide Risk</th>
</tr>
</thead>
<tbody>
<tr>
<td>Beck Depression Inventory. Patient picks best answer.</td>
<td>3 = I feel as though I am very bad or worthless. 2 = I feel quite guilty. 1 = I feel bad or unworthy a good part of the time. 0 = I don't feel particularly guilty.</td>
<td>3 = I would kill myself if I had the chance. 2 = I have definite plans about committing suicide. 1 = I feel I would be better off dead. 0 = I don't have any thoughts of harming myself.</td>
</tr>
<tr>
<td>Symptom Checklist. Patient rates on a 5-point scale from not at all to extremely.</td>
<td>How much were you bothered by blaming yourself for things? The idea that you should be punished for your sins? Feelings of guilt?</td>
<td>How much were you bothered by thoughts of ending your life? Thoughts of death or dying?</td>
</tr>
<tr>
<td>Structured Clinical Interview for DSM-IV-TR. Semistructured interview. Rater selects:</td>
<td>Interviewer asks: &quot;How did you feel about yourself? (worthless?)&quot; If no, “What about feeling guilty about things you had done or not done? (nearly every day?)”</td>
<td>Interviewer asks: Were things so bad that you were thinking a lot about death or that you would be better off dead? What about thinking of hurting yourself?</td>
</tr>
<tr>
<td>Schedule for Affective Disorders and Schizophrenia. Semistructured interview. Rater selects answers on a 6-point scale from not at all to extreme.</td>
<td>Interviewer asks: Do you blame yourself for anything you have done or not done? What about feeling guilty? Do you feel you have done anything wrong? (Do you deserve punishment?) Do you feel you have brought this on yourself?</td>
<td>Interviewer asks: Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.</td>
</tr>
<tr>
<td>Hamilton Depression Rating Scale. Rater selects best answer.</td>
<td>Interviewer rates: Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).</td>
<td>Interviewer asks: When people get upset or depressed or feel hopeless, they may think about dying or even killing themselves. Have you? (Have you thought how you would do it? Have you told anybody about suicidal thoughts? Have you actually done anything?)</td>
</tr>
</tbody>
</table>
| Brief Psychiatric Rating Scale. Rater selects answer on a 7-point scale where 1 = Not present \ 7 = Extremely severe | Overconcern or remorse for past behavior. Rate on the basis of patient's subjective experiences of guilt as evidenced by verbal report with appropriate affect; do not infer guilt feelings from depression, anxiety, or neurotic defenses. | Interviewer rates: Suicidal tendencies, including preoccupation with thoughts of death or suicide. Example: "Were things so bad that you were thinking a lot about death or that you would be better off dead? What about thinking of hurting yourself?"

| Further questions: Assess delusions of guilt or sin. |
| Further questions: Assess gestures, attempts, risk-rescue factors, medical lethality. 0 = Thoughts of suicide absent. |
| 1 = Feels life is not worth living. 2 = Wishes he or she were dead or any thoughts of possible death to self. 3 = Suicide ideas or gesture. 4 = Attempts at suicide (any serious attempt rates 4). |

The tracing of a patient who took an overdose of tricyclic antidepressants is shown in Figure 30–5.

**Electroencephalography**

A history of brain injury or head trauma is often an indication for an electroencephalogram (EEG) in the work-up of mental status changes or psychiatric symptoms. Depending on the patient’s presentation, the patient with new-onset psychosis should also have an EEG because partial complex seizures may produce psychosis. Symptoms suggesting temporal lobe epilepsy (TLE) (Figure 30–6), such as hyperreligiosity, hyposexuality, and hypergraphia, also indicate that an EEG should be obtained, including nasopharyngeal leads, to best evaluate electrical activity in the temporal lobes. One must keep in mind that the yield on a single EEG may be low and that consultation with an epileptologist may be indicated in cases in which suspicion for TLE is high. EEGs may be useful in the assessment of insomnia and other sleep disturbances. Abrupt onset of psychiatric symptoms such as psychosis, mania, or personality change, or the presence of visual, olfactory, or tactile hallucinations suggest central nervous system dysfunction, which may warrant evaluation by electroencephalography.

**Brain Imaging**

Several methods of brain imaging are available to assist in diagnostic assessment. Table 30–17 lists the indications for brain imaging.
CT scans and magnetic resonance imaging (MRI) can be used to assess brain structure, and are useful in detecting such abnormalities as mass lesions (central nervous system neoplasms, certain infections, and hemorrhage), calcifications, atrophy, or areas of infarction. Mass lesions should be suspected when the patient has papilledema, or has focal or lateralizing abnormalities such as focal weakness, unilateral disturbances in reflexes, and increased pupillary size. Other situations that call for brain imaging include the work-up of a patient with dementia to look for brain atrophy or lacunar infarctions; the evaluation of new-onset psychosis, acute onset of aphasia or memory loss, and neglect syndromes; the evaluation of normal-pressure hydrocephalus (a syndrome characterized by a wide-based gait, dementia, and urinary incontinence); and demyelinating conditions.

Whereas CT and MRI provide visualization of brain structure, functional MRI, positron emission tomography (PET), single photon emission computed tomography (SPECT), and regional cerebral blood flow allow investigators to study brain functioning by assessing which areas of the brain are stimulated during various types of mental activity. At present, these tests have greater relevance to research than they do to clinical assessment. [For a complete discussion of brain imaging, see Chapter (33).]

### Special Assessment Techniques

In certain situations, special assessment techniques may be indicated in the psychiatric evaluation of patients who are unable or unwilling to cooperate. These situations include the assessment of patients who are mute, have amnesia, or intentionally provide false information. In general, special techniques are employed only after all conventional ways to obtain the necessary information have been exhausted, including the use of other informants where available and appropriate.
Figure 30–5 *D*Tricyclic antidepressant overdose. The patient was a 25-year-old woman who took 500 mg of imipramine (Tofranil) 4 h before the 5 pm tracing was recorded. The three standard limb leads show wide QRS complexes of varying morphology. The exact rhythm cannot be determined. She had severe hypotension at this time. Fifteen minutes later, the tracing shows probable supraventricular rhythm with intraventricular conduction defect. [Source: Chou TC (1991) Electrocardiography in Clinical Practice, 3rd edition. WB Saunders, Philadelphia, PA, USA, p. 481.]

[Source: Wyngaarden JB, Smith LH, and Bennett JC (1992) Cecil Textbook of Medicine, 19th edition. WB Saunders, Philadelphia, PA, USA, p 2208.]
Hypnosis can aid in the recovery of repressed memories. For example, a patient who presents with a conversion symptom may be able to recall the forgotten traumatic events that precipitated it. The usefulness of hypnosis is limited by the patient’s susceptibility to the procedure and by concern that the interviewer’s suggestions can produce false memories [see also Chapter 94].

Another approach available for similar purposes is to use a sedative during the interview to produce disinhibition and allow the patient to speak more freely or to access otherwise unavailable memories. Intravenous amobarbital sodium is the best known of the medications used for this purpose. Caution must be exercised to avoid oversedation, to monitor for side effects of the medication, and to ensure that the interviewer does not inappropriately influence the patient’s answers.

The assessment of a patient who is suspected of intentionally providing false information or malingering can become uncomfortable and problematic because it may require techniques that seem at odds with the establishment of the therapeutic alliance. A careful assessment of the patient’s motives and the potential for secondary gain, confronting the patient with inconsistencies, physical assessment of implausible somatic complaints, and the use of other informants, prior medical records, and other documents can all help establish the validity of what the patient is saying. When the case involves the commission of a crime, an assessment of the patient’s capacity to understand his or her actions may be important for the disposition plan.

However, because psychiatric evaluation depends on what the patient tells the interviewer and there are few objective means of clarification, outside of forensic settings it is best for the interviewer not to be overly concerned about the possibility of being intentionally misled. Establishing the truthfulness of the patient’s story usually takes place over an extended period.

**Treatment Planning**

The psychiatric evaluation is the basis for developing the case formulation, initial treatment plan, initial disposition, and comprehensive treatment plan.

**Case Formulation**

The case formulation is the summary statement of the immediate problem, the context in which the problem has arisen, the assessment of risk, and the tentative diagnosis. The latter two areas are described next in more detail.

**Assessment of Risk**

The assessment of risk is the most crucial component of the formulation because the safety of the patient, the clinician, and others is the foremost concern in any psychiatric evaluation. Four areas are important: suicide risk, assault risk, life-threatening medical conditions, and external threat. While comprehensive and accurate documentation is always a goal for mental health professionals, it is of particular relevance in the area of risk assessment. Furthermore, risk should be viewed as existing on a continuum from very low risk to very high risk, as opposed to merely being present or absent.

While no one source can be said to define the standard of care for assessing the risk of violence or suicide in psychiatric patients, it is clear that psychiatrists need to be able to conduct an adequate risk assessment. Authorities in this area argue that an individual clinician’s clinical experience may not be enough, and particularly in the area of violence risk assessment, the risk assessment tools grounded in evidence-based risk factors are increasingly being employed to supplement the clinician’s experience and judgment (e.g., HCR-20, see Webster et al. 1997; VRAG, see Quinsey et al. 2006). The use of such instruments, among other things, increases the likelihood of a comprehensive assessment and decreases the chance that a clinician will engage in an idiosyncratic assessment that does not take into account the robust risk factors identified in the psychiatric literature.

**Suicide Risk**

The risk of suicide is the most common life-threatening situation that mental health professionals encounter. Its assessment is based on both an understanding of its epidemiology, which alerts the clinician to potential danger, and the individualized assessment of the patient. Suicide is the 11th leading cause of death in the US. In the past century, the rate of suicide has averaged 12.5 per 100,000 people. Studies of adults and adolescents who commit suicide reveal that more than 90% of them suffered from at least one psychiatric disorder, and as many as 80% of them consulted a physician in the months preceding the event. An astute risk assessment therefore provides an opportunity for prevention.

For those who complete suicide, the most common diagnoses are affective disorder (45–70%) and alcoholism (25%). In certain psychiatric disorders, there is a significant lifetime risk for suicide, as listed in Table 30–18. Panic disorder is associated with an elevated rate of suicidal ideation and suicide attempts but estimates of rates of completed suicide are not well established. Additionally, while rates of suicide for individuals with anorexia nervosa appear high, there is a great deal of comorbidity with other psychiatric disorders that puts these individuals at risk for suicide, making the increase in risk associated with anorexia difficult to estimate.

Suicide rates increase with age. Women attempt suicide more often than men, but men are three to four times more

---
likely than women to complete suicide. Whites have higher rates of suicide than other groups.

A patient may fit the diagnostic and demographic profile for suicide risk, but even more essential is the individualized assessment developed by integrating information from all parts of the psychiatric evaluation. This includes material from the present illness (e.g., symptoms of depression, paranoid ideation about being harmed), past psychiatric history (e.g., prior attempts at suicide or other violent behavior), personal history (e.g., recent loss), family history (e.g., suicide or violence in close relatives), medical history (e.g., presence of a terminal illness), and the MSE (e.g., helplessness, suicidal ideation).

The most consistent predictor of future suicidal behavior is a prior history of such behavior, which is especially worrisome when previous suicide attempts have involved serious intent or lethal means. Among the factors cited as having an association with risk of suicide are current use of drugs and alcohol; recent loss, such as of a spouse or job; social isolation; conduct disorders and antisocial behavior, especially in young men; the presence of depression, especially when it is accompanied by hopelessness, helplessness, delusions, or agitation; severe anxiety and/or panic attacks; certain psychotic symptoms, such as command hallucinations and frightening paranoid delusions; fantasies of reunion by death; and severe medical illness, especially when it is associated with loss of functioning, intractable pain, or central nervous system dysfunction. Table 30–19 lists the risk factors for suicide. It should be noted that assisted suicide is now more openly discussed among people with terminal illnesses and has gained some measure of acceptability. Nonetheless, the vast majority of people who are bereaved or suffer from a serious medical illness do not end their lives by suicide. Adequate end-of-life care should forestall requests for assisted suicide. Although suicidal intent may be lacking, patients who are delirious and confused as a result of a medical illness are also at risk of self-injury.

It is essential to be clear about whether the patient has passive thoughts about suicide or actual intent. Is there a plan? If so, how detailed is it, how lethal, and what are the chances of rescue? The possession of firearms is particularly worrisome, because nearly two-thirds of documented suicides among men and more than a third among women have involved this method.

Factors that may protect against suicide include convictions in opposition to suicide; strong attachments to others, including spouse and children; and evidence of good impulse control. The usefulness of so-called “suicide contracts” as a prevention strategy is questionable, and may create a false sense of security, particularly at the beginning stages of treatment before a strong therapeutic alliance has been established.

In addition to the assessment of risk factors, it is important to decide whether the possibility of suicide is of immediate concern or represents a long-term ongoing risk.

### Risk of Violence

Unlike those who commit suicide, most people who commit violent acts have not been diagnosed with a mental illness, and data clarifying the relationship between mental illness and violence are limited. The most common psychiatric diagnoses associated with violence are substance-related disorders. Conduct disorder, antisocial personality disorder, and psychopathy (a construct referring to a severe form of antisocial personality [Hart 1998]), by definition, involve aggressive, violent, and/or unlawful behavior. Sex offenders may meet criteria for a paraphilia, such as pedophilia or sexual sadism.

In the absence of comorbid substance-related disorders, most people with such major mental illnesses as affective disorders and schizophrenia are not violent. But data from the National Institute of Mental Health Epidemiological Catchment Area Study suggest that these diagnoses are associated with a higher rate of violence than that found among individuals who have no diagnosable mental illness. The MacArthur Violence Risk Assessment Study found that this was only true for psychiatric patients with substance abuse (Steadman et al. 1998).

Table 30–20 lists the risk factors for violence. As with suicide, the best predictor of future violence is a history of past violence. Information from the psychiatric evaluation that helps in this assessment includes the present illness (e.g., preoccupation with vengeance, especially when

accompanied by a plan of action), psychiatric history (e.g., childhood conduct disorder), family history (e.g., exposure as a child to violent parental behavior), personal history (e.g., arrest record), and the MSE (e.g., homicidal ideation, severe agitation). Other predictors of violence include possession of weapons and current illegal activities. There is considerable overlap between risk factors for suicide and those for violence, and similar to suicide, the use of specialized instruments and tools to assess the risk of violence, particularly in forensic settings, is becoming more widespread.

**Life-Threatening Medical Conditions**

It is essential to consider life-threatening medical illness as a potential cause of psychiatric disturbance. Clues to this etiology can be found in the present illness (e.g., physical complaints), family history (e.g., causes of death in close family members), medical history (e.g., previous medical conditions and treatments), physical examination (e.g., abnormalities identified), and MSE (e.g., confusion, fluctuation in levels of consciousness). Laboratory assessment, brain imaging, and structured tests for neuropsychiatric impairment may also be essential.

Probably, the most common life-threatening medical situations that the psychiatrist evaluates are acute central nervous system changes caused by medical conditions and accompanied by mental status alterations. These include increased intracranial pressure or other cerebral abnormalities, severe metabolic alterations, sepsis, toxic states, and alcohol withdrawal (see Table 30–21). Patients may be at risk of death if these states are not quickly identified.

### External Threat

Some patients who present for psychiatric evaluation are at risk as a result of life-threatening external situations. Such patients can include battered women, abused children, and victims of catastrophes who lack proper food or shelter. Information about these conditions is usually obtained from the present illness, the personal history, the medical history, and physical examination.

### Differential Diagnosis

The differential diagnosis is best approached by organizing the information obtained in the psychiatric evaluation into five domains of mental functioning according to the disturbances revealed by the evaluation (see Table 30–22 and the subsequent chapters in this section for more detail). After organizing the information into these five domains, the psychiatrist looks for the psychopathological syn-

includes assessments on each of the five axes of DSM-IV-TR disturbances described. A complete diagnostic evaluation includes assessments on each of the five axes of DSM-IV-TR (Table 30–23).

Disturbances of consciousness, orientation, and memory are most typically associated with delirium related to a general medical condition or a substance use disorder. Memory impairment and other cognitive disturbances are the hallmarks of dementia. Results of the history, physical examination, laboratory testing, and brain imaging often help in defining the specific etiology. Neuropsychological testing is particularly useful in the diagnosis of subcortical dementia, such as that caused by Huntington’s disease and HIV infection. Dissociative disorders and severe psychotic states may also present with disturbances in this domain without evidence of any medical etiology. Cognitive impairment caused by mental retardation is established by intelligence testing.

Disturbances of speech, thinking, perception, and self-experience are common in psychotic states that can be seen in patients with such diagnoses as schizophrenia and mania, as well as in central nervous system dysfunction caused by substance use or a medical condition. Disturbances in self-experience are also common in dissociative disorders and certain anxiety, somatoform, and eating disorders. Cluster A personality disorders may be associated with milder forms of disturbances in this domain.

Disturbances of emotion are most typical of affective and anxiety disorders. These disturbances may also be caused by substance use disorders and general medical conditions. Mood and affect disturbances accompany many personality disorders and may be especially pronounced in borderline personality disorder.

Physical signs and symptoms and any associated abnormalities revealed by diagnostic medical tests and past medical history are used to establish the presence of general medical conditions, which are coded on Axis III. When a medical disorder is causally related to a psychiatric disorder, a statement of this relationship should appear on Axis I. Physical signs and symptoms may also suggest diagnoses of mood or anxiety disorders or states of substance intoxication or withdrawal. Physical symptoms for which no medical etiology can be demonstrated after thorough assessment suggest somatoform or factitious disorders or malingering, although the possibility of an as-yet-undiagnosed medical condition should still be kept in mind.

Information about behavior and adaptive functioning is useful for diagnosing personality disorders, documenting psychosocial and environmental problems on Axis IV, and assessing global functioning on Axis V. This information is also useful for diagnosing most psychiatric disorders, which typically include criteria related to abnormal behaviors and functional impairment.

When all information has been gathered and organized, it may be possible to reach definitive diagnoses, but sometimes this must await further evaluation and the development of a comprehensive treatment plan.
Initial Treatment Plan
The initial treatment plan follows the case formulation, which has already established the nature of the current problem and a tentative diagnosis. The plan distinguishes between what must be accomplished now and what may reasonably be postponed for the future. Treatment planning works best when it follows the biopsychosocial model and takes into account the treatment time frame, e.g., brief hospitalization, long-term outpatient care, etc.

Biological Intervention
This includes an immediate response to any life-threatening medical conditions and a plan for the treatment of other less acute physical disorders, including those that may contribute to an altered mental status. Prescription of psychotropic medications based on a patient’s presenting symptoms, psychiatric history, and tentative diagnosis is the most common biological intervention.

Psychosocial Intervention
This includes immediate plans to prevent violent or suicidal behavior and address adverse external circumstances. An overall strategy must be developed that is both realistic and responsive to the patient’s situation. Developing this strategy requires an awareness of the social support systems available to the patient; the financial resources of the patient; the availability of services in the area; the need to contact other agencies, such as child welfare or the police; and the need to ensure child care for dependent children.

Initial Disposition
The primary task of the initial disposition is to select the most appropriate level of care after completion of the psychiatric evaluation. Disposition is primarily focused on immediate goals. After referral, the patient and the treatment team develop longer term goals.

Hospitalization
The first decision in any disposition plan is whether hospitalization is required to ensure safety. There are times when a patient presents with such severe risk of harm to self or others that hospitalization seems essential. In other cases, the patient could be managed outside the hospital, depending on the availability of other supports. This might include a family who can stay with the patient or a crisis team in the community able to treat the patient at home. The more comprehensive the system of services, the easier it is to avoid hospitalization, and many mental health systems offer intensive outpatient services to avoid expensive inpatient care. Because hospitalization is associated with extreme disruption of usual life activities and by itself can have many adverse consequences, plans to avoid hospitalization are usually appropriate as long as they do not compromise safety.

Day Programs, Crisis Residences, Supervised Housing, and Assertive Community Treatment
Housing interventions provide ongoing supervision but at a lower level than that available within the hospital. They are most often used to treat patients with alcohol and substance use disorders and/or severe mental illness. Crisis housing can be useful when a patient cannot safely return home, when caregivers need respite, and when the patient is homeless. Other forms of supervised housing usually have a waiting period and may not be immediately available.

There are many different types of and names for day-long programming, including partial hospitalization, day treatment, psychiatric rehabilitation, and psychosocial clubs. Depending on the nature of the program, it may provide stabilization, daily medication, training in social and vocational skills, and treatment of alcohol and substance use problems. Long-term day programs should generally be avoided if a patient is functioning successfully in a daytime role, such as in a job or as a homemaker. In these instances, referral to a day program may promote a lower level of functioning than the patient is capable of.

Assertive community treatment (ACT) is an intensive program that operates 24 hours a day and combines outreach techniques with a broad array of services to keep patients in the community. ACT teams can often be utilized to prevent, substitute for, or reduce the time spent in inpatient psychiatric treatment.

Outpatient Medication and Psychotherapy
The most common referral after psychiatric evaluation is to psychotherapy and/or medication management. In office-based settings, the psychiatrist decides whether she or he has the time and expertise to comprehensively treat the patient, and makes referrals to other practitioners as appropriate. Hospital staff usually have a broad overview of community resources and refer accordingly. There are high rates of dropout when patients are sent from one setting to another. These can be reduced by providing introductions to the treatment setting and/or conducting follow-up to ensure that the referral has been successful.

Comprehensive Treatment Planning
The psychiatric evaluation usually continues beyond the initial disposition. The providers assuming responsibility for the patient, who may be inpatient staff, outpatient staff, or private practitioners, complete the evaluation and take responsibility for developing the comprehensive treatment plan. This plan covers the entire array of concerns that affect the course of the patient’s psychiatric problems. In hospital settings, the initial treatment plan is usually completed within 24–72 h after admission, depending on applicable standards, followed by a comprehensive treatment plan after more extensive evaluation.

The comprehensive treatment plan usually includes more definitive diagnoses and a well-formulated management plan with central goals and objectives. For severely ill or hospitalized patients, every area is usually covered (Table 30-24). It is best for the patient and, as appropriate, the family, to have input into the plan. The comprehensive treatment plan guides and coordinates the direction of all treatment for an extended time, usually months, and is periodically reviewed and updated. For more focal psychiatric problems (e.g., phobias, sexual dysfunctions) and more limited interventions (e.g., brief interpersonal, cognitive, and behavioral therapies in office-based practices), the comprehensive treatment plan may focus on only several of the possible areas.

### Conclusion

The psychiatric evaluation is a method of collecting present and past psychological, biological, social, and environmental data for the purpose of establishing a comprehensive picture of the patient’s strengths and problems, including the psychiatric diagnoses, and developing treatment plans. It is the essential beginning of every course of psychiatric treatment and, when carried out successfully, integrates a multimodal approach to understanding mental illness and providing clinical care.

### References

### Further Reading

There are currently only about 6000 child psychiatrists in some sort of clinical practice in the United States, whereas there are between 7 and 12 million children with psychiatric illnesses, as identified by DSM-IV-TR criteria (Costello and Pantino 1987, US Public Health Service 1999). Most of these children will not see a child and adolescent psychiatrist, and their care must be undertaken by general psychiatrists, other physicians, and mental health care providers. The assessment of children and adolescents should utilize the caution and competence required by a physician treating an individual patient with a broad concern for that patient’s development in the context of family, school, and society.

Medical care must begin with diagnosis. A comprehensive diagnostic assessment should address the medical and psychiatric condition of the child; the child’s emotional, cognitive, social, and linguistic development, and the nature of the child’s relationship with his or her family, school, and social milieu. Evaluations must address not only a narrow consideration of clinical diagnosis but also a larger set of issues that are truly biopsychosocial. Children are today served by a variety of individuals and agencies, each possessing their own particular agendas and separately approaching physicians and other consultants. These agendas must be recognized and served, given today’s consumer-oriented society. At the same time, we have a responsibility to those individuals seeking our professional services to educate them with the wider range of concerns that may be affecting a given child’s life or families’ outcome.

Referrals may come from a variety of various social and legal agencies such as courts and departments of human services, from teachers or schools, or from other physicians. Many referrals come directly from parents, who are often generally very concerned about their child’s impaired functioning and suffering. They may bring to the process a mixed heritage of concern, guilt, and shame, frequently fearing that they will be judged as they seek assistance help. Concurrent with this are often ambivalent feelings of love and frustration toward a difficult child. The duty of all psychiatrists is to recognize all these needs and address them in a manner that is not only authoritative but also tactful and empathetic.

Elements of the Psychiatric Evaluation

Collateral and Preliminary Information

Today, most children who are seen by child and adolescent psychiatrists have already received a great deal of attention from other professionals. To fail to gather information from them prior to a formal evaluation is a serious mistake, leading to wasted time and frustrated relationships. If at all possible, it is usually most efficient to speak directly with a referring professional. This is especially true in the case of primary care physicians, who may have a long-standing relationship with the child and family. Other mental health professionals referring a child usually have conducted their own evaluation. Children’s school records can be a rich source of information about a child’s cognitive and emotional development. Examination of this data can enrich an evaluation; similarly, failure to do so can lead to embarrassing lapses.

Often a child and adolescent psychiatrist’s first personal encounter in evaluating/assessing a patient is with another professional—a clinician, or an educator, or a case worker who has sought the examination. The enormous value of their information has already been discussed. The clinician must also recognize the sensitivities of these people: they may be grateful for the opportunity to talk with the psychiatrist and eager in their expectation of the evaluation.
perhaps even to an unrealistic degree. At the same time, the act of seeking consultation may, at least unconsciously, signify to them a failure on their part. They may be concerned that their relationship with the child or family will in some way be disrupted or supplanted, or that they will be criticized by the psychiatrist.

Parents

Parents bringing their child to a child psychiatrist come with a rich and often contradictory mix of feelings. Frequently they reach the psychiatrist at the end of a long, complicated process of evaluations and treatment attempts. They are almost invariably concerned over their child’s condition and prospects. In a way that may be difficult for those who are not parents to understand fully, they may have many fears about the consequences of a psychiatric referral, as do referring professionals. They may feel that they will be judged or, in extreme cases, that their children will be removed from their care. In a more subtle way, they may also worry that their relationship with their child will be supplanted or superseded. They may be concerned about the moral and philosophic basis of the psychiatrist’s approach, fearing that parental ethical standards and religious beliefs may in some way be contradicted. Sometimes, they may have unrealistically optimistic or hopeful fantasies of “absolution” of unconscious guilt, or of quick cures. Usually, more often than not, parents have no idea of the specifics of psychiatric assessment or treatment. Their opinions have been formed by mass media and public prejudice. The psychiatrist needs to understand how the parents feel about the referral and what they expect to gain from it.

A great deal of information should be obtained collected from parents, since they know the child best. The details of this data collection, including various outlines for its organization, are described elsewhere in this book. Most child and adolescent psychiatrists today use a traditional medical format to organize their data, with headings such as Chief Complaint, History of Present Illness, Past Medical History, Family History, and Review of Systems. More often than not, the specifically medical aspects of these data are already available. Not infrequently, however, families have not received regular primary medical pediatric care. In these cases, it is incumbent on the psychiatrist as physician to take a comprehensive medical history in addition to acquiring other information. In all these areas of questioning, psychiatrists collect data as do all other physicians, usually attempting to organize the information in a chronologic fashion. What is unique about a psychiatric evaluation is that physicians find not only the specific data but also their affective implications. In other words, they inquire to find out not only as to what specifically happened but also how it made the child or family members feel and what consequences/impact it had on their lives.

Another area of inquiry of particular relevance to physicians treating children is the developmental history. The developmental history elicited by a psychiatrist should in many ways be similar in depth and breadth to that obtained by a developmental pediatrician, with a special emphasis on the social and affective consequences of developmental phenomena. Some developmental processes or stages may inherently be more or less comfortable for some parents, and that there is a wide range of variation in the degree of comfort and discomfort that development engenders. Developmental assessment begins with asking about a child’s conception, prenatal history and delivery. Questions about fine and gross motor milestones, speech development, toilet training, sleep patterns are essential. In older children stages of puberty and physical growth and the feelings around it should be asked. Finally, we must be aware of the great variations in developmental patterns and expectations found among different cultures.

The family has an immense and profound influence on the development of each of its members and may be viewed as a unique entity. It is therefore invaluable, as part of a comprehensive psychiatric observation, to ideally spend some time in the company of the entire family. The opportunity to observe firsthand how the members of a family act with each other/interact can be enriching for a clinician attempting to understand the consequences of each family member’s behavior on the others. In addition, if this observation is done early, it may serve as a more comfortable entrance to the evaluation process for a shy or otherwise recalcitrant child or otherwise uncooperative family member.

Meeting the Child

In practice, most clinicians develop a somewhat personal style of interaction usually formed by psychodynamic and interactional approaches and also more structured empirically. Clinicians in any setting realize that, outside of the specific requirements of a structured interview instrument, they need to be flexible in their approach. The schemes that we use for reporting an interview are generally best conceived as devices for retrospective organization rather than templates for an interview. This is of particular importance with children. Any pediatrician knows that in the course of a physical examination one does what one can when one can. Similarly, in the psychiatric interview with the child, one must be flexible and mobile both verbally and physically. The order of the interview will depend on the age of the child. Generally, younger children will be seen after meeting with the parents alone. Adolescents often are given the choice to be seen first without parents. This allows for the development of rapport and trust with the teenager. Information from the parents is usually obtained with the teenager in the room, as they can be suspicious about what the parents will say about them.

One of the most vital elements of an initial psychiatric interview with the child is the establishment of a productive relationship—in other words, “making friends.” The clinician must keep in mind how children feel in the context of an interview. Children may share or reflect the same complicated and ambivalent mixture of fear, shame, hope, and misapprehension that their parents bring to the process, and they often have not been fully prepared by the parents or others for the interview. Such preparation, if it can be done by parents prior to bringing the child in, can be helpful. Many children, in our experience, have been told nothing at all, other than “Come along, we are going to see someone.” Or they may have been told that they are going to see a doctor, which can convey fears of injections and manipulations. Some children may have been led to assume that the evaluation is part of a punitive process. Others may feel that by virtue of referral they have been singled out in some way as “weird” or “crazy.” Concurrently, the child may expect to
see the physician as some sort of remote, distant, punitive, or bizarre figure. All these issues must be promptly investigated and addressed in a developmentally appropriate fashion for a productive interview to ensue.

How one handles the above issues is affected by one’s own personality and training, and by the circumstances of the child and family. Preschool children are seldom able to sustain any type of formal interview, although they may answer some questions during play activities or while “on the run.” Their preoperational style of cognition makes the standard interview format, with its attention toward consequence and chronology, irrelevant. One assesses these children through observation and interaction. By contrast, the school-age child often will have some comprehension of the psychiatrist’s role. It may help to introduce one’s self as a “talking doctor” or “problem doctor” who deals with the problems that many children have (generalization may make the child feel less singled out) through conversation as well as traditional somatic treatments, and who does not give injections in the office setting. Older children and adolescents can often be asked directly about why they were brought to evaluation, as well as their opinions about its necessity and desirability. With school-age children, an initial request about what sort of problems they may have encountered in their life may be met with diffidence or avoidance. In this instance, simply playing together at some mutually acceptable activity may be an important first step. Older children and adolescents may at this time be able to tolerate tactful questions or the mention of other material or information. They will still benefit from the opportunity to talk or interact about areas that they like, perhaps later in the interview. A frequent icebreaker employed by child and adolescent psychiatrists is drawing. Children who are seated in the waiting room while their parents are being interviewed can be given the opportunity to draw a picture of their family or some other subject of interest to them, their family, or another picture. Such a drawing can serve as both a projective device and a conversation starter later in the process. Of course, children can also be encouraged to draw at other times during the interview.

In many instances, children do not respond to a standard, direct, complaint-centered line of questioning, even after several attempts by the clinician. The clinician is then best advised to relent and ask the child to talk about more general aspects of his or her life. The patient can be encouraged to tell the physician about his or her family, including each individual member and their relationship. School can easily be discussed touching on academic issues, behavior aspects and a child’s social life. In doing so, the clinician can often assemble a broad picture of the child’s life as well as specific medical information about phenomenology. Some areas will need to be more directly pursued, usually later in the interview when a presumably more trusting relationship has been established. These include items that are considered part of the mental status examination such as the presence of affective symptomatology (including suicidal ideation or plans) and psychotic phenomena (including hallucinations, delusions, or ideas of reference). Not every child needs to be asked about these things, since for some merely inquiring in an initial interview can be disruptive or fearful. Nevertheless, these issues must be pursued if there is any indication of a disorder in the given area. Suicidal ideation in particular must be pursued in the context of any affective disorder. Other important behavioral areas such as sexual behavior, drug abuse, and health-risk behaviors may also need to be pursued.

The issue of confidentiality warrants special consideration. Psychiatrists must use their clinical skill to moderate two conflicting demands: the child’s right as a patient to confidentiality as versus the right of parents and, in some instances, other agencies or institutions to be aware of the child’s needs and requirements. In our experience, most parents want to know what their child is thinking; concurrently, most children want their parents to understand them, although they may prefer to conceal some specific details. Younger children may be told that they have a right to hold secrets, but that their parents also have a right to know what in general is going on in their lives. Adolescents and their parents may be told that they have a right to confidentiality, but that some information involving a serious risk to themselves or others could be shared. Conflicts over confidentiality often overlie larger family issues that, when addressed, make the confidentiality issues moot or irrelevant.

Child and adolescent psychiatrists have traditionally been encouraged to pursue children’s fantasies in the course of an evaluation. The different approaches to this trend tend to be highly personalized by each clinician and may include asking a child for three wishes, positive or negative animal identifications (what animal would you like or not like to be), story completion, response to fables, or other techniques. Few if any of these approaches, as used idiosyncratically in an unstructured interview, have ever been validated. They should not be treated as sources of empirical data in and of themselves. They can, however, be useful probes to seek other information that can be validated and, more important, that relates to specific emotional concerns of an individual child or adolescent.

Often nonmedical professionals refer to the psychiatric evaluation as the “mental status exam,” but in fact this examination is not always used in evaluating children and adolescents. However, a formal mental status examination must be pursued when there is evidence of a thought disorder. In these instances, the type of examination used with adults generally suffices for adolescents as well. In younger children, the mental status examination is often a list of observations that is retrospectively organized from the content of the interview thus far described (the outline of this examination is summarized in Table 31–1). In most child and adolescent psychiatric assessments, these parameters are not all specifically cited but are mentioned as part of the narrative or may be drawn from inference by the reader. If the patient in question possibly has a major thought or affective disorder, however, specific adherence to this outline may be useful.

**Standardized Assessment Instruments**

Structured interviews, rating scales, and questionnaires and structured interviews have become more widely used in child and adolescent psychiatry in recent years, although their primary venue remains in research settings. In many cases, a comprehensive evaluation can be conducted and reported without requiring the use of these instruments; and some instruments may require a degree of time and expense unavailable outside a research setting. However, as diagnostic
Mental Status Examination Outline

provides Child and Parent Domain. The total stress score is filled out and yields information on a wide variety of disruptive behavior. The PSI is a straightforward 36-item questionnaire that can be completed by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available).

Eyberg Child Behavior Inventory (Eyberg and Ross 1978) provides Child and Parent Domain. The total stress score is filled out and yields information on a wide variety of disruptive behavior. The PSI is a straightforward 36-item questionnaire that can be completed by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available). The PSI is filled out by parents of children ranging in age from 1 to 12 years (a short form is available).

There are limitations to the strictly intrapersonal perspective, however, since children should be understood within the context of their lives (Mooney and Harrison 1987). Assessment techniques should be broad and should include measures that assess the child “in action.” Psychological techniques suggested for this type of assessment include parent/teacher questionnaires, intelligence and achievement testing, drawings, projective testing, child questionnaires, behavioral assessment, play observations, and family interaction.

Parent and Teacher Questionnaires

Questionnaires are often quick effective ways to get important information from people not directly available such as teachers, for the assessment. They also provide a way to ascertain information directly from the parents. The Eyberg Child Behavior Inventory (Eyberg and Ross 1978) is a straightforward 36-item questionnaire that can be completed by parents of children who are 2–7 years of age (Eyberg and Ross 1987). The Eyberg is relatively simple to fill out and yields information on a wide variety of disruptive behavioral problems.

The Parenting Stress Index (PSI) by Abidin (1995) is filled out by parents of children ranging in age from 1 month to 12 years (a short form is available). The PSI provides Child and Parent Domain. The total stress score combines both domains and allows for an analysis of the source of stress. This, can be used to assess the degree to which the child’s behavior is stressful versus the difficulty the parents have in adjusting to their parenting roles. PSI results are also helpful in communicating with parents; the clinician can report, for example, that the parents provided the information that they feel depressed or that they are experiencing communication barriers with their spouse. With this technique, parents are less likely to be defensive, and the clinician can be more reflective and understanding rather than intrusive.

The Child Behavior Checklist is completed by parents or teachers of children ages 4–16 years (Achenbach 1991a, 1991b, Achenbach and Rescorla 2000). The accompanying additional Youth Self-Report Scale is completed by youngsters from 11–18 years of age. These questionnaires have the advantage of providing a behavior profile which gives information on the following dimensions: withdrawn; somatic complaints; anxious/depressed; social problems; attention problems; delinquent problems; and aggressive behavior. While not strictly diagnostic, they can provide an additional source of information or suggest areas to be explored further in the clinical interview. Separate forms are used for boys and girls ages 4–5, 6–11, and 12–16 years.

There is a wide variety of attention deficit hyperactivity disorder (ADHD) rating scales available for ascertaining the presence of symptoms at school, home and other settings. Detailed description of the merits of various tests is discussed by Collett et al. (2003). The most widely used is the Conners’ Rating Scales-Revised. It provides teacher- and parent-rating ADHD index and can be used to assess children at risk for this disorder. The McCarney Attention-Deficit Disorders Evaluation Scale Conners (1997) is an empirically based attention-deficit hyperactivity disorder (ADHD) index that can also be used to assess children at risk for ADHD (McCarney 1995). It condenses the three subscales of inattentiveness, impulsivity, and hyperactivity to two scales: inattentiveness and impulsivity/hyperactivity. These scales can also be used to assess improvements from the use of psychoactive medication.

Cognitive Assessment

Intelligence testing is both overrated and underrated. There is often too much emphasis on intelligence quotient (IQ) scores per se. Psychological tests provide a wide range of information regarding strengths, weaknesses, learning style, and needs. There are many important personal qualities that intelligence tests do not measure, however, such as creativity, determination, and persistence over a period of time.

There are many factors other than difficulties with intellectual functioning that can lead to low IQ scores. These include cultural or linguistic differences: distractibility or anxiety, refusal to cooperate, and disabling conditions.

Intelligence tests give a wide range of information about children’s abilities in several areas of functioning. The Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV) provides subtest and composite scores in specific verbal and performance areas as well as an overall cognitive score which reflects representing general intellectual ability (Wechsler 2003). This revised edition has updated norms, new subtests, and greater emphasis on discrete domains of cognitive functioning.
The Wechsler Preschool and Primary Scale of Intelligence-III (WPPSI-III), available since 2002, offers an assessment of the intelligence of children ages 2 years, 6 months through 7 years, 3 months (Wechsler 2002). Like the other Wechsler tests, it provides an overall cognitive score as well as scores for verbal and performance abilities (Tables 31–2 and 31–3).

Ability testing provides us with information on the pattern of strengths and weaknesses that can affect the student’s ability to function in the classroom, including the special needs and learning style of the student. These in turn, can influence the presentation of any psychiatric symptoms.

Children who have marked discrepancies between verbal and performance IQ scores can experience difficulty functioning in the classroom. Any child who has a severe deficit may be significantly affected even if many other subtest scores are average or above average. Children with high verbal scores but low performance scores struggle with the production of work in the classroom. Children with high performance scores and low verbal scores are often impulsive, action-oriented individuals who have difficulty reflecting or using language to process their experience. Some children such as the learning disabled (LD)/gifted child, have complex combinations of cognitive abilities. Children with ADHD often score low on one or more subtests of the WISC-IV. There is tremendous variability in the relative abilities of children with ADHD, which can negatively affect performance on structured tests in varied ways.

The Stanford-Binet Intelligence Scale-Fourth Edition (WJ-IV) (Woodcock et al. 1989 and the Wechsler Individual Achievement Test-Second Edition (Smith et al. 2002) provide information on basic academic skills such as reading, writing, and math ability.

A quick assessment of intelligence is provided by the Kaufman Brief Intelligence Test (K-BIT) (Kaufman and Kaufman 1990). This can be used for children, adolescents, and adults from the ages of 4–90 years. It requires 15–30 minutes to administer and has only two subtests. It can be useful for establishing a baseline of intelligence but does not provide in-depth information on strengths and weaknesses.

The Woodcock-Johnson-III Tests of Achievement (WJ-III) (Woodcock et al. 1989 and the Wechsler Individual Achievement Test-Second Edition (Smith et al. 2002) provide information on basic academic skills such as reading, writing, and math ability.

The diagnosis of developmental disabilities or mental retardation should never be made on the basis of IQ alone. Rather, one should consider the pattern of strengths and weaknesses on IQ tests, assess adaptive and other behaviors, and use common sense.

When assessing a child, it is important to seek multiple sources of data, including information on the child’s personal and social sufficiency at home, at school, and in the community. The Vineland Adaptive Behavior Scales can be used to measure communication, daily living skills, socialization, and motor skills in children from birth to 18 years and 11 months of age or in low-functioning adults (Sparrow et al. 1984).

### Drawings

The seminal work of DiLeo (1983) describes the relationship between characteristics shown in the patient’s drawings and the patient’s behavior and overall development. Drawing can be used both as a means of assessment and as a means of initiating and maintaining a relationship with a child.

Clinicians use subjectivity as well as their clinical experience in interpreting children’s drawings. The age and developmental level of the child must be considered in the interpretation of drawings, and the clinician should be familiar with what is normative for specific developmental

levels. Drawing characteristics that have interpretive significance include the use of space, the quality of line, orientation of objects, shading (as an indicator of anxiety), integration of the human figure drawings, symmetry and balance, and overall style. Drawings are also reflective of cognitive development. The drawing of a person “yields an overview of intellectual maturity.” The Draw-a-Person test (DPT), the Kinetic Family Drawing (KFD) by Burns and Kaufman (1972), and the House-Tree-person test (HTP) by Buck (1970) are systematic approaches to the assessment of children’s drawings.

**Child Questionnaires**

The Children’s Depression Inventory (CDI) is the most widely used popular child questionnaire for assessing depression in children. It was developed by Kovacs (1992) based on the Beck Depression Inventory for adults. The long form has 27 items, and a short form (CDI-S) has 10 items. It is suitable for children ages 7–17 years of age and requires only a third-grade reading level, the lowest of any childhood depression measure.

The Child Anxiety Scale (CAS) can be useful in some instances for children 5 through 12 years of age. (Gillis 1980) It involves 20 straightforward questions in which a child marks on either a red circle or a blue circle. It can be administered by the clinician or with an audiotape.

The Sentence Completion Test for Children is a simple, two-page sentence completion form with 25 items, useful for children ages 5 through 12 years. It may be read out loud or filled out in writing by the patient. Incomplete Sentences Blank forms are useful for young people in high school or college (Rotter 1977). They provide insight into emotional state and inner feelings that might not be verbally expressed in a direct interview.

To aid in assessing teens for substance abuse issues, the adolescent form of the Substance Abuse Subtle Screening Inventory (SASSI) is available for ages 12 through 18 (Miller 1990). Many teenagers will give significant information regarding substance abuse habits on a questionnaire when they may volunteer no information in an interview.

**Play Observations**

Children use play as their natural medium for self-expression and as an avenue for cognitive development. It can, therefore, be useful to incorporate some opportunity to observe unstructured play in child assessment procedures. Typically, a dollhouse, large blocks, puppets, and vehicles can be used. Children’s personalities are revealed in the way that they approach these toys. Straightforward observation of their behavior can indicate how they typically behave in similar situations.

Singer (1973) has described how fantasy allows children to delay gratification and to deal more effectively with frustration, which in turn has implications for their success in the classroom. By studying preschool children, Parten (1932) identified five ways that children play: (1) in solitary play, children are unaware of others and play alone; (2) in onlooker play, children watch others play; (3) in parallel play, children play side by side with little interaction with others; (4) in associative play, children interact and share; and (5) in cooperative play, they relate to each other, helping and taking turns. Piaget described three types of play—practice games, symbolic games, and games with rules—through which children learn the rules of social exchange and enhance their sense of competence and self-esteem (Pulaski 1976).

**Family Interaction**

Family interaction should be an important consideration in any assessment of children. Family sessions can be utilized for diagnostic purposes and are also particularly useful when working with children and their parents to teach child management techniques for externalizing disorders such as ADHD and oppositional defiant disorder (ODD). In each family, however, the child’s role strongly affects his or her feelings, attitudes, and behaviors, and clinicians should assess these characteristics when planning for treatment. Baumrind (1991) demonstrated that a child’s personality characteristics are closely related to the structure of that child’s family, and Hetherington and Parke (1986) compared parenting styles with children’s behavior and self-esteem.

It is important for clinicians to assess parental warmth and emotional availability. These two factors are important to the child in terms of seeking approval. Parents showing these traits may be more likely to teach alternative social responses to the child. Clinicians should also evaluate parental control. Parental restrictiveness or permissiveness can lead to difficulties in child functioning. A permissive family can cause problems of neglect and may also harm a child’s adaptive ability. Authoritarian family approaches may have the advantage of preparing children to deal with rules and limits but the disadvantage of limiting overall individual competence. Finally, one must recognize the profound effect of extended family interaction, both for children who have an intact nuclear family and for those who are being raised by other family members including grandparents. Often, extended family members play a large role in the upbringing of a child.

**Educational Assessment**

Unfortunately few children receive an educational evaluation which may be an extremely useful part of the child’s assessment and rehabilitation, especially as psychiatric treatment progresses. An educational assessment takes into account a child’s psychiatric diagnosis and how they contribute to learning difficulties and are the basis for development of an educational plan to ensure a child’s academic success.

Children are asked to learn basic academic and social skills upon which their performance is judged and compared to that of other children. If children succeed, they learn that success provides opportunities and social status. If, on the other hand, they fail for whatever reasons their self-esteem can be diminished and they learn about failure and restricted opportunities. Professionals involved with children who are experiencing difficulty in school must understand the devastating impact that school failure has on a child’s life and act quickly to resolve the situation.

The educational assessment of children is a specialized process that directly addresses overall academic achievement. The assessment process must be a collaborative approach, which includes not only the teachers, parents, diagnosticians but also the child. The child must be not only the subject but a part of the process. The outcome of any
assessment should provide information that allows teachers, parents, and others to create positive learning environments that allow students to assume control of their own academic destiny. The performance of the child is not viewed in isolation but as part of a large ecosystem with many interdependent variables.

Individuals who conduct educational evaluations are often called diagnostic educators. They must be able to collect the data needed to identify a learner problem and then use those data to devise educational intervention strategies. The diagnostic educator identifies and analyzes the child’s learning patterns and helps the classroom teacher to implement instructional methods specific to the child. The teacher must understand the cause and nature of learning disabilities as well as methods of accommodating them in the classroom. The diagnostic educator uses a school-based problem-solving team to help facilitate change in attitudes, approaches, and assessment of outcomes. The educational diagnostician’s role involves interpreting performance in the classroom, and teaching experience often validates these individuals’ credentials.

**Indications for an Educational Evaluation**

The psychiatrist often can request an educational evaluation when there is a question about school performance or the need to adjust a child’s educational program. The problem may be a new issue or a chronic or crisis situation. The cause of problematic behavior must be identified and an intervention plan developed. Whatever the difficulty, it is important to remember that children cannot usually develop coping mechanisms on their own or adjust their school environment to help them better meet expectations. If professionals are reluctant to obtain an assessment there can be misdirected, inefficient, and often disappointing results.

**Legislation and Rights**

Children with disabilities have a legal right to a free and appropriate education, and schools are legally obligated to fulfill these needs although they may resist fulfilling this obligation due to limited resources. Parents often require the assistance of mentors and professionals to ensure that their children’s needs are in fact met. Historically, classroom teachers have assessed children by trying to discover what they do or do not know and why they have learned some things and not others. If a teacher is skilled and the school system supportive, this method can be effective. The individual capabilities of the teacher and the random sensitivity of the system, however, do not ensure that all children experiencing problems in school will be appropriately identified and provided with the necessary adaptations.

The enactment of US Public Law (PL) 94-142, the Education of Handicapped Children Act of 1975, improved this process, mandating that all children ages 5–21 years with an identified handicap will have a free and appropriate education. It outlined procedures to determine eligibility for special education services and appropriate programming. The law was revised in 1990, in 1997, and reauthorized in 2004 and has been renamed Individual with Disabilities Education Act (IDEA) (Ohio Department of Education 2004). This legislation emphasizes educating children in the least restrictive learning environment possible, one that can provide inclusion in the general curriculum. The legislation also provides a specific set of procedures for identifying a child’s disability and determining an appropriate educational plan. Refer to Table 31–4 for more detail. Any child suspected of a disability must have a multifaceted evaluation (MFE), which assesses all areas related to the suspected disability, and an individualized education program (IEP) conference to review the MFE data, determine eligibility for special services, and define the least restrictive learning environment possible.

IEP = individual education program

Schools must provide by law an MFE for any child suspected of having a disability. The referral can be made by the parents, school personnel, or community agency personnel. If parents are making the referral, they should do so in writing, indicating that they suspect that their child has a disability and requires an MFE. If the school district refers the child, the parents must be contacted by the school and asked to give their consent to evaluate.

The school is obligated to hold an IEP conference to review the results of the MFE, determine eligibility for services, and, plan an appropriate education program. This meeting must include parents as joint decision makers. Once a child is enrolled in special education, the school district is obliged to conduct an annual review of the child’s progress and notify parents of current IEP goals. A reevaluation by
the school district is mandated every 3 years. Parents should be notified about and informed about this process. It should be noted that all too often the initiation of a thorough educational assessment requires initiative on the part of the parents.

**The Educational Evaluation**

The purpose of the education evaluation is to gather the data necessary for determining eligibility for special education services and to identify specific learning needs and intervention strategies. Eligibility is ultimately a procedural and legal decision that depends on current levels of performance and standardized data; the identification of specific learning needs requires additional data emphasizing an analysis of the student’s learning patterns, the school environment, and other social and cultural influences (Table 31–5).

The components of an educational assessment are background information, descriptive data, test data, and the educational plan. Background information includes school history, pertinent medical history, the presenting problem, the duration of the problem, and the effect the problem has had on the child’s development at home and in school. Test data usually include both norm- and criterion-referenced testing of academic achievement, general knowledge, and specific skill mastery. These instruments may include those that are part of a typical psychological evaluation as described earlier, as well as more specialized measures. Descriptive data, especially classroom observation, can yield information about a child’s behavior, attention, and general ability to adapt to school expectations.

**Educational Plan**

The final component of an educational evaluation is the educational plan, which provides a framework for creating solutions. In general, the educational diagnostician and the teacher must find two solutions: (1) a way to evaluate the child’s knowledge of content that does not employ a weak skill as the method of testing and (2) a plan to improve knowledge and, when possible, deficient skills. In the past, solutions have focused on requiring the child to improve performance through remediation and, of course, “try harder” without meaningful environmental adjustments. Creating a more accessible learning environment that emphasizes strengths and decreases negative outcomes is vital for children with learning problems to succeed. The psychiatrist participates as evaluator, consultant, support, and strong advocate who can be invaluable to the success of an educational plan.

**Laboratory Assessment**

Laboratory assessment has become a more frequent part of psychiatric evaluation in recent years. Often, patients will have already undergone a comprehensive laboratory assessment, even including neuroimaging, by their referring physicians; the burden of further assessment of these patients is thus not borne by the psychiatrist.

Conversely, some patients will have had little if any laboratory workup, and such assessments may be necessary in an orderly, stepwise fashion. For example, patients might receive standard hematologic and chemical screenings prior to exotic endocrinologic and nutritional assessments. Similarly, it is seldom appropriate to seek an expensive and complicated neuroimaging procedure in a patient who has not yet received a neurologic examination.

Given both the immense advances in neuroimaging and the intense media coverage devoted to this progress in recent years, some patients and families will assume that procedures such as computed tomography (CT) or magnetic resonance imaging (MRI) scanning are an essential part of the psychiatric examination. This, of course, is frequently not the case as these interventions are not without risk and cost to family and society. Clinicians are best advised to deal with these demands by recognizing the underlying motivations of concern, anxiety, or entitlement that evoke these requests. At the same time, as physicians, child and adolescent psychiatrists must be aware of the rare but poignant requests. At the same time, as physicians, child and adolescent psychiatrists must be aware of the rare but poignant circumstances in which gross central nervous system pathology, such as vascular malformations and space-occupying lesions, may manifest themselves.

The electroencephalogram (EEG) continues to be useful in the neurobiological assessment of children and adolescents. Among the illnesses relevant for EEG assessment is autism. Differentiation of Landau–Kleffner syndrome, which has a specific treatment from autism, is very important. Since autism has a seizure incidence of about 20–30% with a peak risk for onset in early adolescence; the clinician should consider ordering an EEG as part of a workup for any unusual change in the adolescents clinical condition. EEG differences from normal have been seen in Attention Deficit Hyperactivity Disorder, conduct disorder, and learning disorders but the findings are nonspecific and EEG is generally not helpful for guiding treatment.

**Outcome of the Evaluation**

**Presentation of Findings and Recommendations to Parents and Referring Sources**

In the past, some psychiatrists, perhaps out of a unique conception of confidentiality, have been reluctant or even
reclusive in sharing their findings with others. In some instances, this practice has even been used with patients who may have been told merely to continue bringing their child for treatment. Such positions were, thankfully, relatively unusual, and current demands for consumer orientation and accountability now make them utterly untenable. Parents and referring professionals or agencies are entitled to a concise and comprehensible statement of findings and recommendations. The delivery of this information depends on the needs of the child and the relationship of the child to these individuals or agencies.

As noted previously, parents approach psychiatric evaluation with a rich mixture of concerns, hopes, and fears, which often occur at the time of the interview. We have met parents who could give a verbatim account of their contact years earlier with a professional regarding their child; the affective intensity of this moment seared it into memory. The fashion in which this powerful circumstance is addressed can profoundly affect the subsequent conduct of the patient’s treatment. It is a truism that at such moments, parents may hear only the first thing told to them. Indeed, it often may be enough in one interview to discuss a single major piece of information and attempt thereafter to address its affective consequences. If diagnostic impressions or therapeutic recommendations are complicated, parents may need a frequent restatement of this content, perhaps accompanied by written or audiovisual supplements and aids. Many parents require a series of contacts to fully understand and process this information. Given the limitations in contact imposed by some care-management agencies, it may be helpful to incorporate into these process case managers or other professionals, who have a relationship with the family. In our experience, however, the ultimate responsibility as well as the ultimate effectiveness in dealing with these issues resides with the diagnosing physician. Psychiatrists must first and foremost address the affective consequences of whatever information is being presented. To fail to do so is not only inhumane but is likely to seriously undermine the subsequent physician-family relationship and the family’s compliance with treatment recommendations.

Sharing Information with Other Physicians, Schools, and Agencies

Since many patients seek child and adolescent psychiatrists as a result of a referral from physicians, schools, or other agencies, information must frequently be shared regarding the patient’s condition, prognosis, and treatment. It is axiomatic that information on any patient cannot be released without the expressed (and usually written) permission of the patient or, in the case of a minor, his or her legal guardian. The content of shared information and the manner in which it is communicated should be discussed in advance with patients, families, or guardians. Information should be released only as requested, and psychiatrists should avoid automatic release of entire reports or clinical notes.

In general, referring sources shouldn’t be given detailed information about members of the family other than the patient. This is especially important in educational settings, since many school records are virtually public documents. The type of information shared with a referring physician may be very different from that shared with the school.

Consultation, Collaboration, and Advocacy

Children’s needs are addressed in our culture by a variety of people including but not limited to parents, professionals, and educators. Even when a child has a major mental illness whose psychiatric needs may be paramount, it is usually impossible for a child and adolescent psychiatrist to function alone. The psychiatrist will be asked to consult with other professionals and educators. Such consultation may be an intermittent advisory relationship, or it may involve ongoing collaboration in which child and adolescent psychiatrists and other professionals interact in discipline-specific roles.

In today’s environment of competition for social and educational resources and need for active intervention in the lives of children and families who are in danger, the psychiatrist has a special role of advocacy. This role may evolve as a result of a request by a patient and family or the psychiatrist’s perception that some special intervention or communication is required. Despite the changing and challenged role of physicians in our society, the psychiatrist can still be an important and invaluable agent in the workings of educational, social, and legal systems.

Conclusion

Child and adolescent psychiatry has a unique role within medicine. It provides diagnostic assessment, therapeutic services, consultation, and advocacy for children and their families. In a broad biopsychosocial context, psychiatrists attempt to best meet the needs of children and families by serving in a fashion informed by scientific rigor, personal sensitivity, and social responsibility.

Overview

Neuropsychology is the study of brain-behavior relationships. While psychology is the scientific study of behavior and mental processes, neuropsychology firmly places that study in the context of its underlying neural structures and mechanisms. Neuropsychology makes use of standardized and normed tests, behavior rating scales, and experimental procedures to elucidate brain-behavior relations, and its methods have both clinical and research applications in psychiatry (Keefe 1995, Lezak et al. 2004, Flashman 2004, Seidman 1994). The unique benefit of a neuropsychological approach in patient care is that it facilitates an integrated, biopsychosocial explanation of behavior, combining hypotheses about brain dysfunction with psychometrics and an understanding of the individual’s cognitive strengths and weaknesses, personality, current stressors, and everyday socioenvironmental context to inform patient management. From a research perspective, neuropsychology’s contributions to psychiatry include understanding the cognitive correlates of psychiatric disorders, their relationship to the neuropathology of a disorder, the extent to which they are specific and/or progressive, and their role in treatment (e.g., medication effects, rehabilitation, and therapy) and functional outcome. For example, over the past two decades, schizophrenia has been reconceptualized as a disorder with core cognitive deficits which are not merely complicating comorbidities but intrinsic components of its phenomenology and related neurodevelopmental pathology that are themselves a viable and important focus of treatment (Green 2007, Seidman 1990).

A different approach to understanding brain function involves neurophysiological evaluation. While neuropsychology is particularly useful in identifying intact and disordered components of information processing (e.g., attention, working memory, executive functions) from which brain function is inferred, neurophysiological methods provide more direct measurement of neural processing and events in real time. Its primary method, the noninvasive electroencephalogram (EEG), records the millisecond-by-millisecond electrical activity of the brain that results from neuronal firing (Niedermeyer et al. 2004). Event-related potentials (ERPs) and event-related oscillations (EROs) extracted from the ongoing EEG in the context of an internal or external event or stimulus permit examination of the rapidly changing patterns of brain activities that underlie cognitive function and dysfunction (Gevins 1998). As psychiatry has increasingly integrated cognitive and affective neuroscience into its conceptual framework and practice, the value of experimental and applied neuropsychology and neurophysiology has grown accordingly. This chapter will review the contributions of neuropsychology and neurophysiology to the practice of psychiatry.

Neuropsychological Assessment and Neurophysiological Evaluation

Assessment of Brain Dysfunction by Neuropsychological Testing

Until the 1970s, psychological evaluation of psychiatric patients usually consisted of a psychodiagnostic test battery (Holt 1968). Such assessments were primarily oriented to personality dynamics or diagnostic judgments about “functional” versus “organic” etiologies, depending upon the degree to which a psychiatric patient’s disorder was thought to be associated with obvious brain pathology. Common referral questions included “Is there an organic component?” to a patient’s clinical presentation, and a clinical psychologist would attempt to determine the presence or absence of “organicity” (brain damage) on the basis of pathognomonic signs. Inferences about “organicity” were most often derived from individually administered tests including the Wechsler Adult Intelligence Scale, Bender–Gestalt, Draw-A-Person, Minnesota Multiphasic Personality Inventory, Rorschach, and supplemental memory tests. Although this clinical process had some success in identifying brain dysfunction, its conceptual and empirical limitations were well established by the 1980s (Lezak et al. 2004, Reitan and Wolfson 1993, Seidman and Toomey 1999). Many organic test impairments were associated with confounding factors (e.g., poor motivation, psychosis, low IQ) and thus produced false-positive diagnoses, and many manifestations of brain damage (e.g., language deficits, memory problems) were not reflected in the single visual–motor test (e.g., Bender Gestalt) typically used to assess “organicity,” leading to false-negative diagnoses.

The basic assumption underlying the outmoded concept of organicity—that brain damage is unitary and could be identified by performance on single tests—was faulty (Flashman 2004). Rather, the cognitive and behavioral manifestations of brain dysfunction vary dramatically depending on the kind, size, and location of the neurodevelopmental or acquired pathology, as well as the period of brain development during which it occurs. Other person variables such as age at testing and age at disorder onset, sex, education, and handedness mediate the expression of brain dysfunction on neuropsychological tests (Heaton et al. 1996). The organicity construct and its measurement have been replaced by a more differentiated understanding of brain–behavior relationships and comprehensive neuropsychological approach. In this model, the clinical neuropsychologist attempts to determine whether the clinical picture and test performance data are consistent with a neurobehavioral or neuropsychiatric syndrome (Feinberg and Farah 1997, Flashman 2004).

While the traditional psychodiagnostic battery remains useful in contributing to a meaningful, integrated understanding of an individual that goes beyond psychiatric diagnosis (e.g., personality style/dynamics, assets, liabilities, conflicts, stress tolerance), contemporary neuropsychological assessment is organized around measurement of a broader range of functions and referral questions. Table 32–1 summarizes the broad range of domains of neuropsychological function most commonly assessed. Importantly, neuropsychological assessment requires consideration of neurological (brain) and psychological (behavioral, cognitive, personality) variables, and their interaction with the environment. The two approaches may be appropriately used conjointly when both personality and neuropsychological factors are to be assessed, such as in articulating various aspects of complex neuropsychiatric disorders such as temporal lobe epilepsy (Greenberg and Seidman 1992, Table 32–2) or attention-deficit/hyperactivity disorder (ADHD; Weinstein et al. 1991, Table 32–3). For such cases, a careful evaluation of personality and neuropsychological functions may enhance goal setting and choice of type of psychotherapy or other treatment and rehabilitation interventions (Seidman 1994).

Neuropsychological Examination Compared with Other Examinations

Neuropsychological testing provides information regarding diagnosis; cognitive, perceptual, and motor capacities or deficits; and treatment recommendations (Table 32–4). Experienced clinicians use test data to determine the presence or absence of brain dysfunction, to localize the damage, and to establish the etiology (Müllberg et al. 1996). Moreover, a comprehensive functional assessment can lead to neurologically meaningful subgroups of disorders (as in different types of developmental disorders, verbal and non-verbal) that may have relevance to treatment, such as in the application of different strategies of cognitive rehabilitation or school placement (Weinstein and Seidman 1994).
Common Uses of Neuropsychological Testing

Reliably, validly, and as completely as possible measure the behavioral and cognitive correlates of brain functions.

determine the basis of “adaptive” failures in academic, vocational, social or self-care functioning.

document the nature and severity of neurocognitive deficits.

differential diagnosis—identify the characteristic profile associated with a neurobehavioral or neuropsychiatric syndrome.

clarify the relationship of behavioral or cognitive change to specific psychiatric or neuromedical disorders or treatments.

monitor neuropsychological status in the context of development/aging, recovery, and/or treatment.

describe neuropsychological strengths, weaknesses, and strategy of problem solving.

assess the patient’s feelings about and compensations to a deficit or disorder.

provide recommendations for management, rehabilitation, or treatment.

contribute to legal decision making: competency, criminal responsibility, or civil damages.

Most neuropsychologists, regardless of theoretical orientation, agree on a number of basic characteristics that define clinical neuropsychological evaluations. The goal in a neuropsychological examination is to reflect reliably, validly, and as completely as possible the behavioral correlates of brain functions (Weintraub 2000). The greatest relevance of testing lies in capacity to inform recommendations for everyday living and treatment planning (Lezak et al. 2004). Developmental neuropsychological assessment as applied in work with children is particularly sensitive to issues related to how observed behavior is related to neuromaturational status, developmental history and expectations, immediate environmental demands (including at home and school), and sociocultural context (Baron 2003, Bernstein 2000). In particular, the clinician is oriented to the impact of neuropsychological strengths and weaknesses in school, family, and other settings.

All neuropsychological approaches assess some aspects of intelligence, reasoning and abstraction, attention (sustained and selective), “executive” and self-control functions (set shifting, planning, and organizational capacity), learning and memory (e.g., working memory, declarative), language, perceptual (i.e., auditory and visual) and constructional tasks, and sensory and motor functions. Comprehensive test batteries can be quite lengthy, because the human brain–behavior relationship is quite complex. Test data are interpreted in the context of many factors including the age, sex, education, and handedness of the patient.

Although the data-gathering approach of the neuropsychologist can be well integrated with a psychodynamic orientation (Seidman 1994, Seidman and Toomey 1999), a few distinctions between the approaches are noteworthy. In the psychodynamic approach, the examiner reduces test structure to assess “projective” components and to discern underlying...
motives, wishes, and thought processes (Holt 1968) whereas the neuropsychologist is usually structuring and encouraging, attempting to find out what the patient can best achieve and by what process (Kaplan 1990). Moreover, neuropsychologists conducting a clinical assessment typically make use of the history, symptom data, and medical records, as well as test data per se, rather than relying on test data alone.

The neuropsychological evaluation covers the same functions as the Mental Status Examination used by psychiatrists and neurologists but in a more elaborated, deep, and quantified manner (Strub and Black 1985, Weintraub 2000). When contrasted with the typical Mental Status Examination, neuropsychological testing is the following: broader, in that more differentiated functions are assessed; deeper, in that far more items compose a task or function, usually arranged from simple to difficult; and more quantified, in that there is more sophisticated scoring of data, as well as the provision of normative data on different samples. In addition, the administration of neuropsychological testing is more standardized. The neuropsychologist’s assessment of cranial nerves, sensory–motor function, and coordination (more “elementary” functions) and the neuropsychologist’s assessment of “higher” cognitive functions complement each other well.

Types of Referral Questions in Psychiatry

The neuropsychological examination has three general aims: (1) identification of neuropsychological dysfunction leading to inferences regarding the presence, type, and etiology of brain dysfunction; (2) comprehensive assessment of cognitive, perceptual, and motor strengths and weaknesses as a guide for treatment; (3) assessment of the level of performance over a broad range of neurocognitive functions, for both initial evaluation and measurement of change over time.

Clinical Vignette 2

In this vignette, the neuropsychological examination identified a nonverbal learning disability, attentional problems, and depression and was used to help frame the patient’s psychotherapy. A 21-year-old man was referred with the goal of assessing the reasons for his lifelong school difficulties. It was clear to the referring psychiatrist that the patient had significant conflicts regarding achievement, variable motivation, and problems with assertiveness; however, the psychiatrist suspected that primary cognitive difficulties might be contributing to the picture. On the Wechsler Adult Intelligence Scale—Revised (Wechsler 1981), the patient had a Verbal IQ of 121, a Performance IQ of 100, and a Full-Scale IQ of 113, certainly indicative of college-level intellectual ability. However, he showed significant discrepancies between rather high verbal reasoning abilities and rather poor arithmetic calculation and visual–spatial skills. Moreover, he worked rather slowly on all visual–motor tasks, and his piecemeal strategy (Kaplan 1990) for constructing the Rey–Osterrieth Complex Figure (Osterrieth 1944, Rey 1941) was developmentally immature. He approached the figure by drawing small details, without recognizing the gestalt, and this inefficient strategy appeared to be responsible for his poor reconstruction of the figure on recall conditions. He also demonstrated attentional difficulties on a continuous performance test (CPT) (Rosvold et al. 1956) indicating difficulties in sustaining attention or vigilance. These difficulties were entirely consistent with the results of a pediatric neuropsychological examination done when he was 7 years old, on the basis of which a “developmental perceptual organization disorder” was reported.

Personality testing with the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) (Hathaway and McKinley 1989) and the Thematic Apperception Test (Morgan and Murray 1953) indicated mild depression, poor self-esteem, anxiety about achievement, and a defensive style emphasizing minimization and denial. These traits were reformulated as, in part, secondary reactions to a primary, lifelong learning disability. The patient was effectively treated once or twice weekly with supportive, psychoeducational psychotherapy by a psychotherapist who was sophisticated in combining neuropsychology and psychotherapy. Moreover, he was adjunctively treated with fluoxetine at 20 mg/day, which contributed to considerable improvement. He felt more energetic and decisive and more able to focus and sustain his attention. Over time, this progress led to an improved social life; a more balanced focus on school, work, and play; and better school performance.

Source: Adapted from Seidman (1994).

Differential Diagnosis

Although experienced neuropsychologists may achieve a greater than 90% accuracy in diagnosing brain dysfunction (Milberg et al. 1996, Reitan and Wolfson 1996), the referring clinician needs to discuss with the neuropsychologist the merits of using neuropsychological examination (comprehensive or brief) compared with other methods such as the neurological evaluation or specialized neurodiagnostic techniques. For example, neuropsychological evaluation is labor intensive (a full battery can take as much as 3–8 hours to administer, not to mention scoring, interpretation, and report writing) and is thus expensive. However, the neuropsychological examination is unique in providing a comprehensive, empirically grounded picture of mental function. Neuropsychological evaluation may be especially helpful when the clinician wants both differential diagnostic information and a profile of adaptive strengths and weaknesses or when neuropsychological testing is perceived as a less threatening diagnostic procedure by a patient who is resistant to other testing.

For many disorders, such as Alzheimer’s disease, there are no reliable and valid in vivo laboratory tests, and these can be best diagnosed with the aid of neuropsychological profiles (Moss and Albert 1992). Other disorders, such as schizophrenia or schizophriniform psychoses associated with temporal lobe epilepsy, may present broadly overlapping and confusing pictures on clinical psychiatric and electroencephalographic evaluation that may be clarified by neuropsychological testing. For example, a distinctly focal and lateralized neuropsychological deficit (e.g., verbal memory deficit and mild word-finding difficulty in the absence of other neuropsychological deficits) is more characteristic of temporal lobe epilepsy than of schizophrenia, where the typical deficits are more widespread (Greenberg and Seidman 1992, Seidman et al. 1992).

The neuropsychologist frequently encounters many typical neuropsychiatric differential diagnostic questions, but the conceptual framework of the diagnostic process differs substantially from the organic versus functional dichotomy of earlier approaches. She or he may frame the question,
“Is there neuropsychological deficit consistent with focal or diffuse brain dysfunction?” (i.e., restricted executive deficits associated with frontal lobe dysfunction versus widespread impairment consistent with a dementing process). The neuropsychologist may ask, “Can this clinical symptom picture be correlated with test scores to identify a cluster of deficits characterizing a specific subtype of neurobehavioral syndrome?” (e.g., the high rate of forgetting found in Alzheimer’s disease). Alternatively, the neuropsychologist may conclude that cognitive dysfunction is indeed present but may be static or not essential to the syndrome being evaluated (i.e., developmentally based language problem in a case of adult-onset traumatic brain injury).

**Characterization of Adaptive Strengths and Weaknesses and Treatment Planning**

Perhaps the most clinically useful contribution of the neuropsychological examination compared with that of neurological or other neurodiagnostic evaluation is in providing a broad description of the patient’s capacities and deficits and the impact of these resources and limitations on the patient’s adaptation. This profile is essential for treatment planning, which may include rehabilitation efforts generally and psychotherapy specifically (Weinstein et al. 1991). In the context of a feedback session, a neuropsychological assessment can be a therapeutic process and intervention.

For example, although it may be clear that a patient has schizophrenia, the disorder is heterogeneous with respect to manifestations of brain dysfunction (Seidman 1983, 1990), and it is often helpful to identify the cognitive and behavioral approaches to support success in educational, vocational, and daily living settings (Liberman et al. 1982, Medalia et al. 2003, Velligan et al. 2000). Subtle learning disabilities may be identified in a student who is anxious and depressed about failures in school but is unable to pinpoint the cause. Referrals of this type are wide ranging; they include high school students who have a specific spelling disability, college students who are quite bright but are unable to learn required foreign languages, and graduate students in mathematics, science, or medicine who are failing subjects requiring visual–spatial analysis. All of these people may benefit from counseling about career choice, recommendations for compensatory learning strategies, and psychotherapy to deal with the impact on self-esteem, mastery, and identity (Seidman 1994).

Identification of a neurologically based cognitive deficit may also help a patient come to terms more realistically with narcissistic injuries associated with failure experiences. Some patients are greatly relieved when they learn that the basic origin of their problem is in their brain and not in their mind or “self.” Others, of course, become depressed because they perceive damage to the brain as irremediable. Neuropsychological data can aid the family of a handicapped or vulnerable child (e.g., with schizophrenia or learning disability) by helping them develop realistic expectations for their child so that secondary emotional problems can be minimized and a maximally supportive environment can be constructed (Seidman 1994).

**Assessment of Change Over Time**

A common concern in clinical psychiatry is the assessment of change over time. Changes in cognitive and behavioral functioning associated with aging and development (e.g., mild cognitive impairment, manifestations of dyslexia), progression of or deterioration associated with a disorder (e.g., Alzheimer’s disease, epilepsy, schizophrenia, renal disease, diabetes), recovery (e.g., mild head injury/concussion, neurosurgery, abstinence from substance abuse), or treatments (e.g., medications, electroconvulsive therapy) have important clinical and functional implications. While

---

**Clinical Vignette 3**

In this vignette, the issue of stability of neuropsychological functioning early in the course of schizophrenia and the problem of distinguishing capacity from performance are addressed. As is apparent in Table 32–5, there were dramatic fluctuations over a year when testing was done three times at approximately 6-month intervals. Moreover, changes were not equivalent across tasks; performance on certain tasks was fairly stable and performance on others changed markedly along with the exacerbations and remissions of the patient’s psychosis.

The patient was an 18-year-old single man, right-handed, high school student when his behavior began to deteriorate at the beginning of his senior year. Six months later, he had a florid psychotic episode including acute catatonic symptoms resulting in a 7-month inpatient psychiatric hospitalization. The patient had a good premorbid history, was a better than average student without evidence of learning disabilities, and had no documented neurological problems. However, he was drinking alcohol and using some drugs at least once or twice weekly during the period before hospitalization. He had a normal EEG and a mildly abnormal CT scan including slightly enlarged lateral ventricles, unilateral visibility of the right temporal horn, and prominence of the anterior interhemispheric fissure.

The patient was initially given the neuropsychological battery 4 months (time 1) into his first hospitalization. This was after his acute catatonic symptoms had abated, and he was cooperative with the evaluation. Although he was not fully stable at that time, he was quite testable and had been receiving a stable dose of medication for about 6 weeks (haloperidol, 20 mg/day). His second evaluation (time 2) took place 7 months later, when as an outpatient he was in significant remission and had not been taking any medication for more than a month. The third evaluation (time 3) took place 6 months later, when he had been readmitted after decompensation and was once again taking haloperidol (20 mg/day). He remained quite engageable and cooperative throughout all three examinations, during which he was tested by the same examiner.

In reviewing Table 32–5 it is clear that the overall neuropsychological performance parallels the patient’s change in clinical status, from initial acute psychosis (time 1) to outpatient remission (time 2) to exacerbation of the psychosis (time 3). Whereas he was quite impaired in some areas at time 1 (e.g., verbal fluency at the seventh percentile), his overall picture suggested average intellectual abilities and only mild to moderate attention and conceptual dysfunction.

At time 2, during the patient’s best clinical state, he was dramatically improved in all areas previously assessed but showed significant impairment on the WCST, which had not been previously administered. At time 3, when most of the tests were re-administered, he declined most significantly on the Wechsler Adult Intelligence Scale, less so on other tasks, and remained impaired on the WCST.
Chapter 32 • Neuropsychological Assessment and Neurophysiological Evaluation

There are important psychometric challenges to measuring clinically significant change (Barr 2002, Chelune 2003), monitoring cognitive status by repeated testing contributes to diagnostic and treatment decision making. Baseline testing early in the course of an illness such as schizophrenia or dementia can be compared with later evaluations to clarify the course of the disorder or to assess the impact of various interventions. At present, the considerable value of assessing change in cognition (particularly in clinical trials) is best exemplified by the recent National Institute of Mental Health initiative to encourage development of new pharmacological and psychosocial interventions for cognitive deficits in schizophrenia known as MATRICS (Measurement and Treatment Research to Improve Cognition in Schizophrenia; Green et al. 2004, Marder and Fenton 2004, Nuechterlein et al. 2004). Given that cognitive deficits are increasingly viewed as robust and reliable influences on functional outcome among individuals with schizophrenia, the need for a standard battery to index baseline cognitive deficits and treatment-related changes was recognized and spurred this novel initiative. The MATRICS battery comprises seven relatively independent cognitive domains: speed of processing, attention/vigilance, working memory, verbal learning and memory, visual learning and memory, reasoning and problem solving, and social cognition.

The Flexible, Hypothesis-Testing Approach to Assessment

The assessment of the multiple functions that have been described can be performed with various degrees of depth and flexibility. For example, we have noted that a comprehensive examination may last from 3 to 8 hours, whereas a shortened screening examination may take only an hour or two, covering the same functions more superficially. Moreover, even briefer “bedside” evaluation may be most appropriate for patients who cannot be tested by conventional methods. The increasing prevalence of patients presenting with cognitive disorders (especially elderly patients), combined

with resource limitations, may redefine the way in which neuropsychologists practice. Milberg (1996) noted that evaluations must be “efficient, designed to reflect current knowledge of brain function and the developmental characteristics of older patients.” He suggested that specialized “microbatteries” should be developed to serve as brief, cognitively specific assessment instruments.

This approach has developed over the past decade, as managed care approaches have led practitioners to devise more efficient procedures. The neuropsychologist often begins with a series of short, focused tests and adds others’ as questions need to be addressed in more detail. An example of this is in the assessment of ADHD. In this syndrome, the diagnosis is made by DSM symptoms and history. Yet the clinician may want to address the degree of formal attention or executive dysfunction that is present. This typically leads the examiner to evaluate vigilance (using a CPT), response inhibition (such as by use of the Stroop Test), and organizational skills (such as by use of the Rey–Osterrieth Complex Figure). Because learning disabilities such as reading or arithmetic disability overlap commonly with ADHD (Semrud-Clikeman et al. 1992) and contribute to executive dysfunctions (Seidman et al. 2001) and long-term school outcome (Farazone et al. 2001), it may also be important to add a number of tests to address the presence of co-occurring learning disability. Thus, the examiner may bring in measures of phonological processing (for assessment of dyslexia) (Willcutt et al. 2001) and/or measures of mathematical and spatial ability, to assess nonverbal learning disability (Weintraub and Mesulam 1983).

Neuropsychological evaluations differ not only in length but also in conceptual focus and in selection of the particular instruments that compose a battery of tests. In general, three batteries are used commonly throughout the US: the Halstead–Reitan Battery (Reitan and Wolfson 1993), the Luria–Nebraska Battery (Golden et al. 1980), and a flexible, hypothesis-testing approach typified by the Boston process neuropsychological approach (Goodglass and Kaplan 1979, Holmes-Bernstein and Waber 1990, Kaplan 1990, Milberg et al. 1996). The decision to use one or the other of these approaches depends to some extent on the training of the practitioner, the nature of the referral questions, and a number of other factors discussed in more detail elsewhere (Seidman and Toomey 1999).

Neuropsychological examination requires attention to the outcome of problem solving and, perhaps more important, to the process of performing tasks (Table 32–6).

Reitan and Wolfson (1996) have articulated four types of analyses that clinicians use to evaluate neuropsychological data: (1) level of performance refers to the absolute deviation and dispersion of individual test scores compared with normative expectations and within-patient (across different tests for the same subject) scatter of scores; (2) left–right comparisons are made on sensory, perceptual, and motor performances, presented to, or executed by, the two sides of the body; (3) pathognomonic signs are special features of extremely poor performance or specific clusters of test scores pointing clearly to the existence of discrete disorders; and (4) differential patterns are large arrays of test profiles that are predictive of disease or damage.

The Boston process neuropsychological approach is not a battery of identical items or tests routinely administered, such as the Halstead–Reitan and Luria–Nebraska batteries, but rather reflects a flexible, hypothesis-testing, qualitative approach to neurobehavioral syndrome analysis (Goldberg and Costa 1986). The Boston process approach involves a combination of qualitative and psychometric features that reflects the integration of the behavioral neurological orientation exemplified by Geschwind (1979) and Luria (1980) with the rigorous quantification of the American research tradition in psychology. Many neuropsychologists around the world use variations of the clinical, qualitative process approach in that they have a flexible approach to battery construction in the context of relatively shared neurobehavioral knowledge.

The process approach starts with a small set of core measures and then focuses in more specifically and intensively as hypotheses are developed. On the assumption that neurological dysfunction is reflected in psychological tests, the examiner looks for nonspecific indicators of impairment at the same time that she or he scans for highly selective deficits, or a configuration of deficits that allow the inference that a localized or localized brain dysfunction is present.

Some of the nonspecific (nonlocalizing) deficits found commonly are the following: impairment in conceptual thinking, slowing of ideational processes, perseveration, reduced scope of attention, stimulus boundedness (concretely being drawn to details at the expense of the big picture), and impairment of memory (Goodglass and Kaplan 1979). The set of lateralizing and localizing signs and deficits is too extensive to list completely here but broadly speaking includes disorders of functions previously addressed, such as many aspects of language, attention, visual–spatial performance, and motor ability.

The Boston approach, when oriented toward a relatively comprehensive examination, usually includes but is not limited to tests such as these: the Wechsler Adult Intelligence Scale–III (Wechsler 1997a), the Wechsler Memory Scale–III (Wechsler 1997b), the Rey–Osterrieth Complex Figure (Rey 1941, Osterrieth 1944), a test of visual–constructional and organizational ability, the Wisconsin Card Sorting Test (WCST; Grant and Berg 1948), which assesses various components of executive function such as the capacity to shift set (Goldberg 2001), the Boston Naming Test, a measure of visual confrontation naming ability, and the Category Test, a measure of abstraction ability. Certain tasks or brief batteries may be utilized for specific populations of patients, such as the Dementia Rating Scale.
The process approach utilizes the four basic principles of interpretive analysis described earlier, but emphasizes the way in which the patient attains a score and the preserved functions that the scores reflect rather than the achievement per se. For example, a dynamic serial picture of the process of problem solving is recorded while a patient is putting the block designs together (Figure 32–1). In this way, such behaviors as featural priority (emphasis on details), contextual priority (emphasis on the gestalt), and hemispatial priority (the tendency to work on one side of visual space) can be assessed. Right-hemisphere-damaged patients tend to work on the right side of space and use a detail-oriented strategy, whereas left-hemisphere-damaged patients tend to work in the reverse field and with the reverse strategy (Kaplan 1990, Milberg et al. 1996).

Kaplan (1990) suggested that qualitative data may better reflect an underlying brain lesion, because impairment may be demonstrated even if the final score is correct. This perspective is partially supported by a study by Heaton and collaborators (Adams and Brown 1986, Heaton et al. 1981).

- Right parietal

*Figure 32–1* Block Design: feature versus context. Reprinted with permission from the Journal of Neuropsychiatry and Clinical Neurosciences 2, 72–87, 1990, APPI

They demonstrated that clinicians who rated Halstead–Reitan battery results had better success in classifying brain damage than did a psychometric formula approach relying heavily on level of performance. The authors believed that the superiority of the clinicians was related to their ability to supplement test scores with consideration of the qualitative and configural features of their data. The process approach is consistent with this interpretation in that it is performed by highly trained clinicians rather than by technicians.

The process or flexible approach seems well suited to psychiatry because problem-solving approaches are less likely to be affected by motivational deficits than are level of performance and pathognomonic signs. Process variables are probably less susceptible to conscious faking, as a patient would be unlikely to know the neurological rules governing the process, and may also be less susceptible to practice and repetition effects, which can confound the interpretation of scores. Moreover, it is important to know “how,” not just “if,” a person solves a problem.

**Limitations of Reliability and Validity**

Despite the obvious role of quantification in neuropsychological testing, interpretation of test data ultimately depends on the knowledge base, training, and skill of the clinician. Neuropsychological test scores are an indirect measure of the status of the brain, as contrasted with direct measures of structure by magnetic resonance imaging (MRI) or function by positron emission tomography (PET), functional MRI, or EEG. In a psychiatric setting, where problems of motivation, effort, cooperation, and stage of the illness are ubiquitous, analysis of neuropsychological data must go beyond the level of performance deficits because many studies have shown performance to be especially affected by functional (emotional) factors. Process analyses oriented to focal syndromes and focused on the relative efficiency of the two sides of the body and hemispace may enhance predictive validity.

The patient’s clinical state may change, and repeated testing when the patient’s clinical status is optimal often clarifies the nature of the diagnosis. Selective deficits found in the context of otherwise good performance when patients are tested in their best state can be considered most valid. Neuropsychologists must also take into account the effect of medication on neuropsychological function and distinguish medication effects from the patient’s adaptive ability. Different medications are likely to produce different effects. For example, Trimble and Thompson (1986) have demonstrated that, for epileptic patients and normal subjects, anticonvulsants have negative effects on most measures of neuropsychological testing. On the other hand, Cassens and colleagues (1990) have demonstrated that (traditional) antipsychotic medications have negligible or mildly positive effects on most measures of neuropsychological testing in chronic schizophrenia, with the exception of a negative effect on motor performance. Spohn and Strauss (1989) have indicated that typical antipsychotic medications tend to improve attentional performance, such as on versions of the CPT. The newer atypical antipsychotics, generated a substantial amount of initial enthusiasm as “cognitive enhancers” (Harvey and Keefe 2001), but their putative-increased efficacy compared to first generation “typical” antipsychotics is now considered to be more modest (Mishara and Goldberg 2004).
Neurophysiological Assessment

A variety of techniques are now available that can provide more direct assessments of brain function in psychiatric patients. These include not only neuroimaging techniques (PET scans and functional MR1), but also electrophysiologic measures, such as the EEG and evoked potentials or ERPs. Electrophysiologic measures have the advantage of being economical and noninvasive, and allow continuous monitoring of brain electrical activity with a temporal resolution that surpasses that of neuroimaging measures. The EEG has traditionally been used in psychiatry to screen for brain disorders. In a conventional clinical EEG, a highly trained reader uses visual inspection of brain waves recorded from scalp electrodes. The presence of epileptiform discharges, spikes, or generalized slowing of brain electrical activity is associated with known central nervous system pathology. In patients who have a history of head trauma or where epilepsy is suspected, a clinical EEG should be done to rule out specific neurological disorders (see Table 32–7). When evaluating for epilepsy, several EEGs may be necessary for accurate results because epileptiform activity is not consistently present (Boutros 1992). The EEG can also play an important role in the diagnosis of dementia, delirium, and other cognitive disorders. Generalized EEG slowing in Alzheimer’s dementia is correlated with the degree of cognitive impairment and with decreased regional cerebral blood flow (Hughes and John 1999). In elderly psychiatric patients, a clinical EEG is of value for distinguishing dementia and pseudodementia associated with depression. This is of importance for treatment selection because EEG abnormality in elderly patients is negatively associated with clinical response to antidepressants (Boutros 1992).

Chapter 32 • Neuropsychological Assessment and Neurophysiological Evaluation

Figure 32–3 Graphic sequences. (a) The subject has trouble with smooth continuity in drawing an open square and triangle because of concretely assuming that only two pairs of figures should be drawn attached. The subject later fills in the missing figures. (b) The subject draws an extra loop on the first four reproductions of multiple loops. Perseveration often reflects dysfunction in attention and inhibitory systems, which are relatively common impairments in schizophrenia (Clinical Vignette 4).

Figure 32–4 (a) The Rey–Osterrieth Complex Figure. (b) Patient copy of the Rey–Osterrieth Complex Figure. Although an accurate final reproduction, the patient's approach was segmented and marked by a piecemeal focus on small details to "build up" the whole figure. (c) Immediate "incidental" recall reproduction—the subject was not told to memorize the figure for later retrieval. This is a remarkably fragmented reconstruction in which the patient remembers many of the details in rough proximity to their appropriate place but is unable to create a whole (gestalt). (d) On 20-min delayed recall, the patient lost more information, retaining only individual fragments of the original design. These data were produced by a man with schizophrenia (Clinical Vignette 4), despite substantial clinical and neuropsychological improvement after treatment with clozapine.
Patients who experience their first psychotic episode are also candidates for a clinical EEG because brain lesions and seizure disorders, such as temporal lobe epilepsy, can cause psychotic symptoms that are clinically indistinguishable from functional psychoses. For instance, in a case report (Miyako et al. 2001), a 51-year-old woman with no history of psychosis or epilepsy had an abrupt onset of psychosis with auditory and somatic hallucinations, delusions, and loosening of associations. A clinical EEG revealed epileptiform discharges with diffuse sharp and slow waves, but CT and MRI scans were normal. The patient's epileptiform discharges disappeared following treatment with sodium valproate and she showed complete clinical remission after EEG improvement. This case illustrates how clinical EEG can have an impact on both diagnosis and treatment selection in patients having a psychotic disorder. EEG recordings before, during, and after electroconvulsive therapy (ECT) for depression also have clinical relevance (Hughes 1996, Small 1999). Patients with pretreatment EEG abnormalities may respond less well to ECT (Drake and Shy 1989), and changes in EEG after ECT generally accompany clinical improvement (Sackei et al. 1996). Reviews of clinical EEG findings in childhood and adult psychiatric disorders show that 30 to 60% of referrals have abnormal EEGs (Hughes 1996, Small 1999), which underscores the importance of clinical EEG evaluations in psychiatry.

One of the limitations of routine clinical EEG is that it is dependent on the trained eye of the reader and is therefore subject to human error and may miss subtle abnormalities in the EEG tracing. Digital recording and processing of EEG led to the development of more quantitative approaches to EEG assessment. In quantitative EEG (qEEG), a fast Fourier transform is used to quantify the amount of activity (power) at each frequency in the EEG waveform and this power spectrum is typically divided into four frequency bands—delta, theta, alpha, and beta. Quantitative EEG provides objective, quantitative measures not available by routine visual assessments. A joint report by the American Academy of Neurology and the American Clinical Neurophysiology Society concluded that qEEG techniques should be used “...only as an adjunct to and in conjunction with traditional EEG interpretation.” (Nuwer 1997, p. 284). Although qEEG has received considerable application in psychiatric research, its use in clinical evaluations has been limited. There is general agreement that qEEG can be useful for differential diagnosis of dementia and depression, and in the diagnosis of Alzheimer’s disease (Hughes and John 1999, Rodin 1999). Quantitative EEG can also be of value in screening for possible spikes and seizures in long-term monitoring, for example during sleep or ambulatory EEG recording (Nuwer 1997), and in monitoring the effects of drug treatment on brain activity (Itil 1982). There have also been attempts to develop qEEG measures that could be used as adjuncts for psychiatric diagnosis (John et al. 1988), but additional clinical research is needed to demonstrate its clinical utility in this context (Nuwer 1997, Rodin 1999). In an extensive review of the qEEG findings for psychiatric disorders, Hughes and John (1999) point to the problem of heterogeneity of psychiatric disorders such as schizophrenia, which may account for some conflicting qEEG findings. One of the potential uses of qEEG could be identifying more homogeneous subtypes that share a common pathophysiology. For instance, Sponheim and colleagues (2000) found that a subtype of schizophrenia with a specific qEEG abnormality frequently reported for this disorder, that is, augmented low-frequency and diminished alpha-band activity, showed structural brain deficits and ocular motor dysfunctions not seen in patients without this qEEG abnormality. Techniques for topographic mapping of qEEG measures, using current source density (Tenke and Kayser 2005) or Low Resolution Electromagnetic Tomography (LORETA) (Pascual-Marqui et al. 1994) analyses, are now being applied in psychiatric research and may lead to clinical applications for improving diagnosis and treatment selection.

Brain potentials evoked by auditory stimuli (e.g., clicks or tones) have been used in both clinical and research contexts in psychiatry. Brain stem evoked potentials (BSEPs) refer to seven positive potentials evoked during the first 12 ms after hearing a click. BSEPs have proven useful for assessment of hearing in infants and uncooperative patients, and in the assessment of brainstem lesions and multiple sclerosis (Cesleria and Brigell 1999). A later event-related P3 or P300 potential, typically recorded during an “oddball” target detection task, refers to a positive potential that peaks 300 to 500 ms after onset of an infrequent target tone. The strongest case for the clinical utility of the P3 potential is in aging and dementia (Polich 1999). Longer P3 latency distinguishes patients with dementia from those with pseudodementia secondary to depression, and patients with Alzheimer’s disease from healthy subjects (Ford et al. 1997, Frodl et al. 2002, Polich and Herbst 2000). Although P3 provides a useful index of cognitive efficiency, it has less value for the differential diagnostic of psychiatric disorders such as schizophrenia because it lacks specificity. Earlier negative potentials, in particular N1 or N2, are reduced in schizophrenia, but not in depressed patients or in epilepsy patients and may therefore have greater specificity (Bruder et al. 1998, Ford et al. 2001, Kayser et al. 2001). One of the main obstacles to clinical application of ERPs as well as qEEG in psychiatric diagnosis has been the lack of standardized methods and normative data (Polich 1999), but some progress is now being made in this regard (Thatcher et al. 2003).

A new direction for potential clinical application of neurophysiological measures and neuropsychological tests in psychiatry is the identification of patients within a given diagnostic category who have a specific physiologic or cognitive abnormality and who may respond best to a specific form of treatment (Bruder et al. 1999). There are reports of differences between depressed patients who respond to an antidepressant and those who do not in neurocognitive function (Dunkin et al. 2000, Taylor et al. 2006), qEEG measures (Bruder et al. 2001, Pizzagalli et al. 2001), P3 latency (Alexopoulos et al. 1997), and loudness dependency of auditory evoked potentials (Mulert et al. 2007). This suggests that further research be directed to evaluating the potential utility of these measures as clinical aids for selecting treatments for individual patients. As normative data are acquired and standardized methods implemented, the use of quantitative EEG and ERP measures is likely to increasingly complement the clinical neuropsychological exam.

Summary
This chapter contains a relatively broad overview of the role of neuropsychological testing and neurophysiological
assessment in psychiatric practice. The increased recognition that many psychiatric syndromes (e.g., schizophrenia, ADHD) can be understood as neuropsychological disorders requires greater attention to the functional capacities and deficits of the affected individuals. Moreover, the increasing prevalence of disorders of cognitive functioning, especially in the elderly, is leading to an increased need for assessment. Neuropsychological testing can be helpful in diagnosis, treatment planning, and assessing change over time, such as in response to interventions (e.g., medications). Neuropsychological assessment can include both cognitive and personality measures, so that the patient’s cognitive problems can be understood psychodynamically in terms of meaning, experience, conflict, and adaptive capacity (Seidman 1994). The flexible use of assessment, at the bedside or in extended evaluation, may be of great benefit to both patient and clinician. Neurophysiological assessment can complement neuropsychological testing by allowing a more direct measure of brain functioning, by providing real-time measures of information processing, and by measuring cognition at a more elemental level.

One final note regarding the use of neuropsychological tests in research: neuropsychological tests have many applications in neuropsychiatric research, although caution must be exercised in drawing inferences about brain localization from individual cognitive deficits (Keefe 1995). Our ability to infer the neuroanatomy of any neuropsychiatric disorder from cross-sectional neurocognitive studies is limited by many factors, such as variations in clinical stage or state, the effects of medications, and the interpretive difficulties posed by developmental alterations in brain organization found in many psychiatric illnesses (Goldberg and Seidman 1991). Of course, neuropsychological tests need not be evaluated in isolation, but may benefit from converging evidence in the neurophysiologic domain.

Introduction

The development of noninvasive techniques for assessing brain structure, function, and chemistry has progressed rapidly, since the innovation of computed tomography in the early 1970s through the current generation of imaging methods. We now use a number of neuroimaging modalities in the conduct of psychiatric research, and can state with little fear of contradiction that no other method of neuroscientific investigation has done more to advance our knowledge of the pathophysiology of mental disorders than has in vivo neuroimaging. Moreover, it is now clear that without a practical understanding of commonly employed imaging methods, the psychiatrist cannot stay abreast of our professional literature. This chapter will review common methods of neuroimaging, equipping the clinician with the practical knowledge of imaging techniques needed to digest related scientific articles. We will not review specific imaging-based research findings, leaving that to those chapters addressing the pathophysiology of specific psychiatric disorders.

Beyond the use of imaging in research, we have recently seen the expansion of neuroimaging into clinical psychiatry beyond the traditional role of aiding in the differential diagnosis of neuropsychiatric conditions to rule out a general medical cause (e.g., brain tumor) for altered mental status ("rule out organic"). We will discuss these emerging clinical applications, along with speculations about the future of imaging in clinical psychiatry.

Contemporary neuroimaging modalities can be roughly divided into either structural modalities or functional modalities. Structural modalities are designed to produce anatomic images of the body, and include computed tomography (CT) and magnetic resonance imaging (MRI). Functional modalities produce images that reflect some aspect of physiologic function, and include positron emission tomography (PET), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI), and magnetic resonance spectroscopy (MRS). We may subdivide function imaging into methods that measure regional metabolism or blood flow, versus those that probe specific neurochemical pathways, that is, molecular imaging.

Structural Imaging Modalities

CT

Standard X-ray imaging has been used as a medical diagnostic tool for over a century. X-rays are differentially attenuated, depending on the material through which they pass (higher attenuation in dense material such as bone and lower attenuation in less dense material such as air and fluid). Radiological procedures use different detection systems to quantify attenuation. Standard X-ray procedures involve X-ray generators producing X-rays that pass in a unidirectional manner through tissue and then impact on X-ray sensitive film. CT, developed in the 1970s, is simply the use of standard X-rays with newer technology for acquisition and image reconstruction (Gibby and Zimmerman 1992). CT scanners utilize multiple X-ray generators and detectors (scintillation crystals) arranged in a ring-like fashion; these detectors send information regarding attenuation to a computer. The body part of interest is placed inside this ring and X-rays pass through the tissue in a multidirectional manner. The area of interest is imaged in a slab-wise or slice-wise manner (thus the term "tomography") as it progresses through the CT scanner, the data from which is integrated and processed to produce a completed CT image (see Figure 33–1).

As is the case for many standard X-ray procedures, the use of contrast agents with CT can increase the likelihood of identifying a lesion that may otherwise be missed or provide additional information about the lesion (Osborn 1994). Radiopaque contrast material introduced intravenously allows visualization of lesions that compromise the integrity of the blood-brain barrier (e.g., cerebrovascular accident (CVA), tumor, inflammation) because the contrast leaks from the intravascular space. Contrast media which enhance
the visibility of pathology by CT are typically iodine-based and may be either ionic or nonionic. Ionic contrast is less expensive than nonionic contrast, but is associated with a greater risk of side effects (Gibby and Zimmerman 1992). In addition to allergic and idiosyncratic reactions (Shehadi 1982), chemotoxicity may present as impaired renal function or even renal failure, with important main risk factors being preexisting renal insufficiency, diabetes mellitus, volume depletion, nephrotoxic drug use, and preprocedural hemodynamic instability (McCullough et al. 2006). In the brain, chemotoxic reactions manifest as seizures. Such reactions occur in approximately 1 in every 10,000 cases but may develop in 1–10% of cases in which gross disruption of the blood-brain barrier is present (Witten et al. 1973). Nonionic contrast is less likely to cause idiosyncratic or chemotoxic reactions (Lasser et al. 1997), but the cost remains higher than that of ionic contrast (White and Halden 1986). The clinician might bear in mind that U.S. plaintiff’s attorneys have taken a recent interest in alleged reactions to radiologic or MRI contrast materials.

Advantages and Limitations of CT

1. CT offers excellent spatial resolution (<1 mm) and is effective at distinguishing tissues with markedly different X-ray attenuation properties (e.g., bone vs. soft tissue vs. fluid vs. gas).
2. CT is useful for the detection of acute bleeding (less than 24–72 h old) but less helpful in subacute bleeding (more than 72 h old) and in severely anemic patients (hemoglobin below 10 g/dl), as in both cases the hemorrhage may tend toward becoming isodense with surrounding gray matter (Osborn 1994). In addition, CT is an excellent modality for imaging bone. CT is the imaging modality of choice for acute trauma or when an acute bleed or ischemia is suspected.
3. CT is not helpful in visualizing subtle white matter lesions due to CT’s poor ability to distinguish between the X-ray attenuation properties of different soft tissue densities.
4. CT uses ionizing radiation and thus is strongly contraindicated in pregnancy. Women of childbearing potential should undergo a pregnancy screen prior to having a CT scan.
5. Patient anxiety is usually less during a CT scan than during an MRI scan because the scanning environment is traditionally more open, quieter, and scanning time is brief.
6. CT is best for patients with ferro-metallic implants (e.g., foreign bodies, some aneurysm clips, pacemakers, etc.) as MRI is contraindicated in this patient population.

MRI

MRI does not use X-rays but instead exploits the magnetic properties of hydrogen atoms in water molecules to construct a representation of tissue (Horowitz 1992). An MRI scanner is comprised of coil (or antenna) detectors arranged in a ring-like fashion. Initially during an MRI scanning session, radiofrequency irradiation is produced by the scanner and directed at the body. This results in excitation of hydrogen atom nuclei in body tissue. Next the radiofrequency irradiation source is turned off, resulting in relaxation of the hydrogen atom nuclei. As the hydrogen...
atom nuclei relax, they give off energy that is detected by MRI scanner. Different components of the relaxation process exist and occur at different rates (called T1 and T2) in different tissues. Specific imaging parameters (T1-weighted versus T2-weighted) are selected according to the clinical circumstances (see Figure 33–2). T1-weighted images are typically used for optimal visualization of normal anatomy, and depict gray matter as dark and white matter as light. T2-weighted images (also referred to as proton density images) are typically used to detect areas of pathology. In T2-weighted images blood appears dark (useful for detecting hemorrhaging) because of the paramagnetic properties of iron in hemoglobin while water appears light (useful for detecting regions with increased water content such as tumors or edema).

Gadolinium is used as the contrast medium for MRI studies because of its paramagnetic properties (Bradley et al. 1993). Like CT contrast, it is introduced intravascularly. Once injected, gadolinium alters the local magnetic environment (i.e., tissue relaxation times). The use of MRI contrast highlights vascular structures and aids in the detection of pathology in areas where blood vessel walls or the blood-brain barrier is compromised. Contrast is also used in magnetic resonance angiography (MRA) which creates detailed vascular images without the need for arterial catheterization. Gadolinium causes fewer adverse reactions than does CT contrast, though the role of gadolinium exposure in the evolution of certain severe disorders (e.g., nephrogenic systemic fibrosis) remains under investigation, particularly (as with radiologic contrast media) in individuals with pre-existing renal dysfunction.

Variations in pulse sequence and other parameters form the basis for the variety of available MRI sequences and applications, only a few of which will be discussed herein. MRI can detect the movement of water molecules within tissues, and forms the basis for diffusion weighted imaging (DWI) and diffusion tensor imaging (DTI). DWI is well suited to detecting recent infarction in the brain, and may be used to rule out such strokes in patients with new mental status changes (Albers 1998). DTI is of great interest to psychiatric research because it allows remarkably detailed assessments of white matter tracts, extending researchers’ ability to test hypotheses concerning circuit abnormalities (Mori and Zhang 2006). DTI is based upon the observation that, while water diffuses equally in all directions in a Brownian fashion in gray matter, in axon-rich tissues, that is, major white matter tracts, the predominant direction(s) of water diffusion is defined by the direction in which axons course. DTI therefore indicates the vector and degree of restriction (anisotropy) of water diffusion within white matter-rich tissues, hence is a measure of structural integrity and directionality. Further refinements have allowed imaging scientists to create visually brilliant reconstructions of white matter tracts known as tractography (Figure 33–3).

Virtually all structural brain imaging research utilizes MRI rather than CT due to the superior spatial resolution of MRI. The most straightforward use of MRI in structural brain imaging research is the use of specific structural MRI acquisition parameters to produce morphometric quality structural images that may be used to precisely calculate the volumes of brain structures in individuals.
Advantages and Limitations of MRI

1. MRI provides excellent spatial resolution and superior soft-tissue contrast in comparison to CT (i.e., more useful for the visualization of gray-white matter edges and white matter lesions).
2. MRI is superior for surveying the posterior fossa and brainstem.
3. Fresh blood from an acute bleed (less than 48–72 hr) is not easily distinguished from gray matter, although this has certainly improved with new MR methods. Subacute bleeding (greater than 48–72 hr) or chronic hematomas are easily identified with MRI.
4. MRI does not use ionizing radiation, and so if an imaging study is unavoidable in pregnancy, it is preferable to CT.
5. For the same reason as #4 above, MRI is preferred when a patient requires several serial imaging studies in a short period of time.
6. MRI is contraindicated in patients with ferro-metallic implants because such objects can cause artifacts, shift position or absorb heat within the magnetic field causing burn injuries, and, in the case of mechanical devices such as pacemakers, malfunction within the magnetic field.
7. As many as 10% of patients undergoing MRI scanning experience significant anxiety during the imaging session, although only about 1% of patients are unable to complete an MRI study as a result of claustrophobia (Eshed et al. 2007). This is likely due to a number of factors, including the deep, tunnel-like architecture and noisiness of MRI scanners. Pretreatment of potentially anxious patients with benzodiazepines or other sedatives/hypnotics before undergoing MRI may be helpful in these situations.

CT versus MRI

1. CT is still the modality of choice for patients with suspected acute bleeds or acute trauma.
2. MRI is superior to CT for the differentiation of white from gray matter and the identification of white matter lesions.
3. MRI is superior to CT for the detection of posterior fossa and brainstem pathology.
4. CT is recommended if MRI is contraindicated (i.e., paramagnetic protheses; inability to tolerate scanner time, noise, or confinement).
5. MRI is recommended if radiation exposure is contraindicated (i.e., young children or women of childbearing potential).

Functional Imaging Modalities

PET

PET uses positron-emitting isotopes to quantitate various measures of brain function (e.g., cerebral blood flow, cerebral glucose metabolism, neuroreceptor characterization, etc.) (Cherry and Phelps 1996). As the name indicates, these unstable isotopes emit positrons which then soon collide with the electrons of surrounding atoms. The annihilation event that occurs after a positron collides with an electron produces gamma radiation. These gamma rays are what PET scanners detect. A PET scanner (see Figure 33–4 consists of a ring of scintillation detectors designed to detect gamma rays. Opposing detectors in the ring are coupled to form a coincidence circuit. Following a positron–electron annihilation event, the resulting gamma rays project from one another at 180°. When events are detected by opposing detectors, an annihilation event is presumed to have occurred at some point along the imaginary line connecting the opposing detectors. Lines of response, which localize the annihilation event in tissue, are produced from these coincidence events. Computers sum all of the coincidence events, localize them in tissue, and then create cross-sectional images (tomographs).

One cannot speak generically of a “PET scan”; the particular radioactive tracer used in concert with scanning defines the applications of the test. Different positron-emitting nuclides ( 18 F, 15 O, 11 C, etc.) can be coupled with a number of molecules to produce tracers that are used to quantitate various measures of brain function, and each radioisotope has a characteristic half-life ( 18 F ≈ 110 min; 15 O ≈ 2 min, 11 C ≈ 20 min). For example, 18 F-fluoro-deoxy-glucose (FDG) is used to measure cerebral glucose metabolism (Reivich et al. 1997). FDG and glucose are taken up by cells in the same way and this uptake is proportional to the metabolic demands of the cell. Once inside the cell, both FDG and glucose begin the same metabolic pathway. At a certain point in this pathway, however, FDG is unable to continue and becomes trapped in the cell whereas glucose is able to continue. This trapped FDG, labeled with 18 F so that it can be detected by the PET scanner, serves as a marker of metabolic activity (see Figure 33–5). This is relevant because cerebral glucose metabolism is tightly coupled with neuronal activity.

Figure 33–3 Diffusion tensor tractography image demonstrating major white matter tracts in the human brain. © Wallace-Kettering Neuroscience Institute (See Color Plate IX)
In terms of the actual protocol, this means that a clinical or research subject must engage in the desired mental activity (such as a specific cognitive task, rest, etc.) for about 35 min during which the above uptake process occurs. Only after this point has been reached will the subject move to the scanner for his scan. Thus, FDG PET is ideal for examining regional glucose metabolism during a mental process that can be done fairly continuously over such a magnitude of time. This suits some experiments much better than others.

The isotope $^{15}$O, either inhaled as $^{15}$O-carbon dioxide or injected as $^{15}$O-water or $^{15}$O-butanol in PET studies to measure cerebral blood flow, has a half-life of approximately 2 min. This means that it is washed out of the body in only 10 min (half-life times 5). Thus, in a 2-hr period as many as 12 separate scanning sessions of 1–2 min each can be completed in a single individual. Researchers take advantage of this ability to perform multiple scans within minutes of one another by having subjects perform different tasks (usually including a control condition) during separate scans. Afterwards differences in cerebral blood flow between the scans can be determined; these differences indicate which brain regions were activated or deactivated during each task when compared to the control condition (see Figure 33–6).

Interpretation of clinical PET scans is usually done in the manner traditionally applied to radiologic and MRI images, in which a trained and experienced nuclear medicine physician determines the relative normalcy of the image based on visual inspection. Research scans, on the other hand, are analyzed and interpreted using statistical methods. This may first require the superimposition of the PET image onto a more anatomically precise MRI structural image (“co-registration”). Statistical methods may involve a pixel-by-pixel comparison of an averaged PET brain for the experimental subjects vs. those in the control group (statistical parametric mapping, or SPM). In other cases, analysis may require that researchers may do laborious
manual tracings of the region of interest on each subject’s MRI, creating a mask that is overlaid upon each subject’s PET image from which quantitative values are drawn.

There are now a number of commercial radiopharmaceutical firms that are able to affordably produce and rapidly deliver \( ^{18}F \)-based tracers to hospital or research PET labs (\( ^{18}F \) is the only commonly used isotope with a long enough half-life for such commercial distribution). This trend has dramatically changed the number of PET labs, since the short half-lives of positron-emitting isotopes previously required an on-site cyclotron, radiophysicist, radiochemist, radiopharmacist, etc., the cost of which severely limited the number of labs. Today we find PET scanners—formerly found almost exclusively in university health science centers—in many general hospitals. Labs without a cyclotron are limited almost exclusively to FDG, so clinical and research applications that require tracers other than FDG are still limited to labs with an on-site cyclotron.

There now also exist commercially available PET/CT machines that combine both imaging modalities within the same frame, allowing for essentially simultaneous structural and functional images with automated co-registration. Combined PET/MRI machines are under development as well.

**Advantages and Limitations of PET**

1. PET is the traditional gold standard of functional neuroimaging modalities.
2. Only PET can measure cerebral glucose metabolism.
3. A larger number of radioligands, especially those used for neuroreceptor characterization, are available for PET.
4. PET offers excellent spatial resolution (~4 mm).
5. Even with the advent of commercial radiopharmaceutical firms, PET is still expensive.

**SPECT**

SPECT is most commonly used to construct images of regional cerebral blood flow (see Figure 33–7), although it may be used for neuroreceptor characterization as well. As is the case with PET, SPECT detects gamma rays produced by unstable isotope component of radioligands. However, the gamma rays that SPECT is designed to detect result from...
Advantages and Limitations of SPECT

1. SPECT is more affordable than PET and does not require a cyclotron for production of nuclides.
2. Currently SPECT provides inferior spatial resolution (~6–8 mm) compared with PET.
3. Typically SPECT spatial resolution worsens as one attempts to image deeper brain structures although this has become less of an issue with the introduction of newer generation SPECT cameras.

PET versus SPECT

1. PET provides superior spatial resolution, especially for deeper brain structures.
2. PET offers a broader array of radioligands for use in receptor studies and is the only modality that allows for the measurement of metabolism.
3. SPECT is less expensive than PET and is still more widely available.
4. Multiple PET scans may sometimes be done within a day whereas SPECT is limited to one study per day.

fMRI

Expanding upon the basic principles underlying standard structural MRI, fMRI allows investigators to assess brain function. Using either a standard or, preferably, a high speed MR scanner with specific image acquisition parameters, indices of cerebral blood flow can be measured (see Figure 33–8). While structural MRI studies rely on excitation and relaxation of hydrogen atoms in water, fMRI takes advantage of the paramagnetic properties of hemoglobin to measure blood flow and volume. fMRI is sometimes also known as blood oxygenation level dependent (BOLD) MRI, and the hemodynamic response to neuronal activity is sometimes referred to as the BOLD effect. fMRI has distinct advantages when compared to PET and SPECT and these include:

- fMRI does not expose subjects to radiation and its relative safety has been documented
- The spatial resolution of fMRI is at least equal to if not superior to that of PET
- The temporal resolution of fMRI is vastly superior to that of PET or SPECT. While the temporal resolution of 15O PET is 1–2 min, that of fMRI is limited only by the hemodynamic response to changes in neuronal activation, on the order of 4–6 s.

The major disadvantage of fMRI when compared to PET or SPECT is that no satisfactory techniques for receptor neuroimaging have yet been developed for fMRI, and metabolism cannot be measured directly. As with SPECT, the investigator infers a relationship between neuronal activity and blood flow. While fMRI currently has little to no clinical utility, it may be useful in clinical situations in the future. One area of research that shows particular promise is the use of arterial spin labeling (ASL) with fMRI. This method produces maps of resting cerebral blood flow (Wintermark et al. 2005). Because ASL data can be obtained without exposure to radiation, this technique may be used instead of PET or SPECT for evaluation of dementia or seizures in the future.

MRS

MRS uses specific acquisition parameters and a standard MR scanner just as fMRI does, although MRS measures the levels of various chemicals in the brain (Henry et al. 2001). The technique is very similar to that of nuclear magnetic
Figure 33–8 fMRI activation study where subjects were given either intravenous cocaine or saline at different times. When the saline condition is subtracted from the cocaine condition (see Figure 33–6 for activation study overview), statistically significant activation associated with administration of cocaine was demonstrated in regions associated with the reward circuitry of the brain. Also note that when this study is conducted using a 3 Tesla (unit used to quantitate the strength of a magnetic field) MR scanner, the findings are much more robust than when using a less powerful 1.5 Tesla MR scanner. (See Color Plate XI)

In Vivo Neurochemical Research: Molecular Imaging

A large number of radioligands used for neuroreceptor characterization are available for both PET and SPECT studies. These radioligands generally bind to a specific neurotransmitter binding sites (including post-synaptic receptors, pre-synaptic reuptake sites, enzymatic binding sites, etc), allowing PET or SPECT to quantify the spatial distribution of these sites in the brain. However, the use of MRS for neurochemical research is limited by its lower spatial resolution compared to other neuroimaging modalities.

Magnetic resonance spectroscopy (MRS) utilizes the magnetic moment of atomic nuclei to create images of the brain. By measuring the relative concentrations of various metabolites, MRS can provide information about the metabolic state of the brain. Phosphorus-31 (31P) MR spectroscopy, for example, can be used to measure the concentration of phospholipids and high-energy phosphate metabolites, while proton (1H) MR spectroscopy can measure the concentration of N-acetyl aspartate (NAA), a marker of neuronal activity, and other compounds involved in cell membrane formation and second messenger systems.

Compared to other functional neuroimaging modalities, MRS has less spatial resolution (from 1 to 150 cubic centimeters depending upon the spectra being generated) due to its low sensitivity, although this is improving with the use of higher field MRI scanners. Currently, there is no clinical utility for MRS, though monitoring levels of drugs in the brain may be a future application.
of the binding site of interest. Radioligands are available for characterizing dopamine receptors (including D₁, D₂, and reuptake sites, see Figure 33–9), serotonin receptors (including 5-HT₁A, 5-HT₂, and reuptake sites), benzodiazepine receptors, opioid receptors, and many other receptor systems. These receptor neuroimaging techniques can be used in a number of research paradigms including comparing populations with and without psychiatric illness to elucidate the pathophysiology of the psychiatric illness and perhaps aid in diagnosis as well as for determining pharmacodynamics and pharmacokinetics of available therapeutics and investigational compounds. Lastly, recent work has focused on using PET to study neuronal function at a level deeper than the surface receptors. Preliminary studies show promise for using PET to image second messenger systems and even gene expression (MacLaren et al. 2000).

An emerging form of molecular imaging involves the use of MRI, employing nanoparticulate complexes that include neuroreceptor binding moieties and MR contrast material such as gadolinium or iron. Similar technology is more advanced in other fields of medical research; nanoparticle-based neuropsychiatric MR molecular imaging is still in early stages of development as researchers address technical and safety issues related to the use of nanoparticles, crossing of the blood-brain barrier, etc. As with each new advance in neuroimaging, the possibility of being able to perform serial molecular imaging studies without rate-limiting ionizing radiation creates new possibilities for assessing previously untestable hypotheses.

Other Imaging Technologies
Other neuroimaging techniques that do not rely upon radiation or the magnetic resonance effect are presently used in psychiatric research. Magnetoencephalography (MEG) is such a technique. MEG is based upon the observation (in accordance with Faraday’s Law of Induction and Maxwell’s

![Figure 33–9 Molecular imaging. ¹⁸F-Fallypride is a dopamine receptor radioligand with high affinity for D₂ and D₃ dopamine receptors. The highest concentration of binding is seen in the dorsal striatum (caudate and putamen), followed by the thalamus and temporal and prefrontal cortices. (See Color Plate XII)
equations) that passing a current through a conductor—in the case of a depolarizing neuronal projection—produces a corresponding magnetic field around the conductor. This technique, which was first introduced about 40 years ago, now utilizes an array of super-cooled superconducting quantum interference devices (SQUIDs) contained within an assembly that fits over the subject’s head, to detect these minute magnetic changes associated with cortical activity. While one can argue that this method is more akin to electroencephalography (EEG) than neuroimaging, there has been significant growth in the number of MEG labs performing neuropsychiatric research, and is thus worthy of mention. MEG’s temporal resolution is measured in milliseconds, and may be uniquely suited to examining some disease-related abnormalities in neural circuits.

Diffuse Optical Imaging (DOI) employs near-infrared light, and exploits the infrared absorptive properties of hemoglobin and deoxy-hemoglobin. DOI can thus measure hemodynamic responses in the brain. DOI is inexpensive, portable, and has temporal and spatial resolving abilities that compare favorably to fMRI.

**Clinical Use of Imaging in Psychiatric Populations**

As stated earlier, the use of clinical neuroimaging by psychiatrists has traditionally been limited to structural studies (CT, MRI) to detect neurological lesions or diseases that may produce psychiatric symptoms. We are now seeing clinical imaging applications that may provide solid confirmatory diagnostic evidence for psychiatric conditions, most notably the dementias. When a clinician is contemplating using the various currently available neuroimaging modalities a number of factors must be considered including the indications, risks, costs, advantages, and limitations. This chapter reviews these factors and provides general guidelines for the use of neuroimaging in psychiatric practice.

**Structural Imaging to Detect a Neurological Etiology for Psychiatric Symptoms**

There have been numerous studies, dating back to 1978, assessing the utility of CT imaging in psychiatric populations. Across these studies, which represent a diverse population totaling 1346 patients, 29.5% of patients exhibited diffuse cortical atrophy while 12% of patients exhibited focal abnormalities (Renshaw and Rauch 1999). The likelihood of detecting an abnormal finding increased with age, with an abnormal neurological examination, with an altered mental status, and with a history of head trauma or alcohol abuse. When MRI became available in the 1980s, changes in the neuroimaging literature reflected a shift away from CT and toward the use of MRI in psychiatric populations. To our knowledge, the largest study of the use of MRI in psychiatric populations was conducted at McLean Hospital over a 5-year period and included all 6200 patients who received an MRI during that time (Rauch and Renshaw 1995). Because finding an abnormality following structural neuroimaging is of questionable value if it does not alter the treatment or outcome, this study focused on treatable findings. The study found that 99 patients (1.6%) had unexpected and potentially treatable findings including hemorrhage, temporal lobe cysts, tumors, vascular malformations, and hydrocephalus. Most importantly, multiple sclerosis was newly diagnosed in 0.8% of the subjects, a rate that is approximately 13 times higher than the prevalence of multiple sclerosis in the general population (Lyoo et al. 1996). For those psychiatric patients with newly diagnosed multiple sclerosis in this study, the largest subgroup had been diagnosed with refractory affective illness.

A number of studies have found an increased incidence of white matter lesions, more easily detected with MRI than CT, in psychiatric populations. When subsequent studies also revealed that as many as 30% of healthy control subjects over age 60 have white matter abnormalities of no apparent clinical significance, researchers began to question the relevance of white matter lesions in psychiatric illness. Subsequent evidence was presented which suggested that subcortical and white matter lesions are more prevalent in patients with late life onset depression and psychosis (Becker et al. 1995).

**General Guidelines for Structural Neuroimaging**

On the basis of existing data, we have suggested criteria for appropriate structural brain imaging (Dougherty and Rauch 2001):

1. Patients with acute changes in mental status (including changes in affect, behavior, or personality) plus at least one of three additional criteria:
   - Age greater than 50 years
   - Abnormal neurological exam (especially focal abnormalities)
   - History of significant head trauma (i.e., with extended loss of consciousness, neurological sequelae, or temporally related to mental status change in question).
2. New onset psychosis.
3. New onset delirium or dementia of unknown cause.
4. Possibly for treatment refractory patients.
5. Possibly prior to an initial course of electroconvulsive therapy (may be helpful in identifying lesions that may lead to an adverse outcome such as aneurysms, tumors, arteriovenous malformations, hydrocephalus, and basal ganglia infarction).

We estimate that adherence to the criteria listed above should yield positive findings in 10–45% of cases. However, only 1–5% will produce findings that lead to specific medical intervention. Lastly, if structural neuroimaging is indicated, one should use MRI unless the problem is an acute trauma or an acute bleed is suspected.

**Indications for Use of Functional Imaging in Psychiatric Populations**

Functional neuroimaging modalities include PET, SPECT, and functional MRI, and are now used in clinical situations as aids for the diagnosis of psychiatric conditions, though psychiatric use of functional imaging lags well behind that seen in fields such as cardiology and oncology (including brain tumors). Also, the use of ligands for neuroreceptor characterization is being increasingly used for the diagnosis and assessment of basal ganglia diseases such as Parkinson’s disease. Still, most applications of functional neuroimaging in psychiatry occur in the field of research. However, a clinical role for functional neuroimaging in dementia, traumatic brain injury (TBI), seizures, and possibly other conditions are evolving and showing promise.
Dementia
As characteristic functional neuroimaging profiles emerge for various forms of dementia, the role of PET, SPECT, and MRI in the evaluation of dementia is expanding. For example, Alzheimer’s disease is associated with characteristic hypoperfusion and reduced glucose metabolism in bilateral temporo-parietal regions (see Figure 33–5). Some studies have indicated that SPECT and PET neuroimaging can offer better than 90% sensitivity and specificity in distinguishing Alzheimer’s disease from other kinds of dementia (Silverman et al. 2001, Bonte et al. 2001), though the diagnostic accuracy for fMRI is not as yet well established, somewhat unfortunately because of the convenience of obtaining an additional functional sequence during the structural MRI session that many of these patients will undergo as part of their diagnostic workup. Other dementias such as frontotemporal dementias (e.g., Pick’s disease) and multi-infarct dementia may also be diagnosed by combining clinical evidence with functional imaging findings. With the introduction of cholinesterase inhibitors for treatment of dementia, early diagnosis of Alzheimer’s disease may have greater import than in the past. Some PET studies of healthy older subjects with normal cognitive function who are homozygous for the apolipoprotein E epsilon 4 allele (a gene associated with the development of Alzheimer’s disease) reveal that these subjects have temporo-parietal hypoperfusion before the onset of disease (Small et al. 1995, Reiman et al. 1996). Initiation of treatment with cholinesterase inhibitors or other drugs being developed, in these individuals prior to the onset of symptoms of dementia may prove to be of great value.

Seizures
Some seizures, especially complex partial seizures, are not always detected by EEG. EEG measures cortical surface electrical activity but is less efficacious if the seizure focus is deeper in the brain. PET and SPECT images typically demonstrate ictal hypermetabolism and interictal hypometabolism (Krausz et al. 1996, Theodore and Gaillard 2000). This allows for the detection of seizure foci during the predominant interictal period. To evaluate a possible seizure disorder, functional neuroimaging is usually performed in conjunction with EEG. PET and MEG are also useful for more precise localization of seizure foci in a patient with a known seizure disorder if neurosurgical intervention is indicated. In such patients, fMRI or MEG can be used to preoperatively map functionally critical cortical areas (e.g., language, primary motor cortex) in order to guide surgical excision of epileptogenic tissues while sparing vital functions.

TBI
Psychiatrists often examine and treat patients with psychiatric symptoms who have suffered a potentially etiologic head injury. In some cases, such as those involving severe TBI that was immediately followed by the emergence of psychiatric symptoms, the diagnostic nexus is fairly obvious. But in the 80% of cases that are classified as mild TBI based upon loss of consciousness < 30 min, Glasgow Coma Scores of 13–15, and posttraumatic amnesia < 24 hr, the causal relationship between the head trauma and subsequent psychiatric problems may be less obvious. In such cases, functional imaging may offer more useful information than that provided by a structural imaging study alone. Injured brain tissue, after the acute stage, may show metabolic depression and reduced perfusion on FDG PET and SPECT, respectively, although research findings have been thus far inconsistent (Belanger et al. 2007). fMRI shows promise as well though with a smaller evidence base. In terms of structural imaging, DTI and another MRI variant, magnetization transfer imaging (MTI), both seem to show greater diagnostic sensitivity than the more typically ordered T1- or T2-weighted sequences. Expert testimony concerning neuroimaging evidence and TBI has now become a fairly common phenomenon in forensic psychiatric practice. Such evidence is often presented to mitigate guilt in criminal defendants, or to support claims of psychic injury in civil litigants.

Clinical Use: Final Comments
There are psychiatrists, some of whom have SPECT imaging suites within their offices, who obtain functional imaging studies across diagnostic groups in their clinical practices. Interpretation is most typically done by visual inspection by an experienced clinician rather than by using statistical methods, and clinical decisions such as medication selection are sometimes based upon these results (poster by Pavel et al. 2005). While such clinical decision-making may lack the statistical foundation found in neuroimaging research, it remains to be seen whether these practitioners are pioneers or simply represent false starts.

Summary
Neuroimaging technology has evolved considerably during the last few decades, and has done more to advance our understanding of the neurobiology of mental disorders than any other neurobiological method. Currently available neuroimaging modalities have increasing clinical utility in psychiatric populations. Although there are still substantial limitations on the amount of information that neuroimaging provides in the clinical setting, the continued evolution of neuroimaging technology offers great promise for the future.

Consciousness, orientation, and memory are three closely linked and interdependent biological processes: a person cannot be oriented without intact memory; memory is related critically to one’s level of consciousness. Correspondingly, these three functions are mediated or affected by many of the same neurotransmitters and neuroanatomical structures (Mesulam 1990). However, recent developments have established important distinctions between even consciousness and attention (Koch and Tsuchiya 2006), undermining the notion that consciousness is entirely identical to those cognitive processes upon which it depends.

The usual definition of cognition (from the Latin cognitio) is an intellectual process by which knowledge is gained by perceptions or ideas. In essence, cognition is the means by which an individual knows or relates to the world. Cognitive changes due to cerebral dysfunction have been well described historically. Hippocrates, in the 5th century BCE, ascribed all mental and emotional activity (including mental illness) to the brain. Soranus, in 100 AD, described phrenitis, a disease associated with acute fever, involving foolish gesticulations, disturbed perceptions, and occasional unresponsiveness. Soranus attributed this condition, which most would now call delirium (see the following text), to a disturbance of the brain (Ackernecht 1959).

Nature of Consciousness
A confusing array of terms has been used to describe consciousness, including awareness, attention, arousal, and vigilance (Benson 1994). Semantics aside, consciousness poses difficulties for precise understanding. Consciousness is readily evident in oneself but not necessarily in others, it is difficult to define, and it has no clear utility. Prominent among current models of consciousness is that of a relatively passive perceiver of ongoing mental activity (Kinsbourne 2006, Tannenbaum 2006, Seth et al. 2006). Consciousness is not universally regarded as a “sensibly continuous” stream ala William James (1890), but, may, on the contrary, consist of distinct fragments of experience. Consciousness corresponds to a gamma synchrony of around 40 Hz, roughly corresponding to the frames of mental activity that are experienced by the highly trained meditator (Hameroff 2006).

Levels of Consciousness
Most pathological conditions of forebrain or midbrain structure or function can affect the individual’s level of consciousness. A change in consciousness manifests itself functionally in the way the person responds to the surrounding environment. In their classic monograph on stupor and coma, Plum and Posner (1982) classified the spectrum of changes in consciousness as alterations of “stimulus-response” (Table 34–1).

This model provides a practical method for the physician to classify levels of consciousness. Accordingly, alert wakefulness (or the normal state) is a condition in which a subject is able to respond immediately and appropriately in all sensory modalities to stimuli. As consciousness becomes increasingly impaired with a dulling of alertness and cognitive functioning, responses become delayed or incomplete and require increasing external stimulation until no response, or only primitive responses, can be elicited. Even at the coma stage of depressed consciousness, there may be many levels of consciousness according to the patient’s ability to respond to stimuli. The Glasgow Coma Scale (GCS) (Table 34–2) is very widely used to rate coma severity and to monitor the process of recovery (Taesdale and Jennet 1974, Gabbe et al. 2003).

Glasgow Coma Scale (GCS) Total 3–15

The GCS is a simple measure that assesses a patient's motor responses, eye-opening, and verbal responses. The minimum score of 3 reflects a fully impaired level of consciousness while a score of 14 (maximum 15) indicates the patient is conscious, conversant, and oriented, although recent memory may still be impaired. One does not awaken from coma suddenly as from sleep, but through a much more gradual and step-wise process. Once a patient has achieved verbal response when recovering from concussion, the Galveston Orientation and Amnesia Test (GOAT) and other instruments provide more detailed assessment of orientation and memory for events before and after brain injury, and is a useful measure with more detailed scaling to evaluate a patient's cognitive status (Levin et al. 1979, Tate et al. 2006). The duration of coma and severity of memory loss after brain insult [posttraumatic amnesia (PTA)] predict the extent of recovery and degree of residual neurological impairment (de Guise et al. 2006).

A classification of levels of consciousness that is limited to deficits, however, omits some disturbances seen in psychiatric illness. A broader perspective of alterations in consciousness also encompasses increased stimulus-responsiveness, as in hypervigilance (Silverman 1968). Many psychiatric conditions associated with increased anxiety or arousal are also associated with hypervigilance (Tucker et al. 1969, Harrow et al. 1972). A hypervigilant individual may respond indiscriminately to stimuli and become distracted or unable to focus attention (Table 34–3). Thus, vigilance, like arousal, more generally follows the well-known inverted U association of arousal and performance: some amount increases performance, but excessive amounts detract from performance (e.g., Sjoberg 1977). Hypervigilance can be induced by stimulant drugs (e.g., amphetamines and cocaine), is seen in paranoid psychosis, and is characteristic of posttraumatic stress disorder.

Catatonia is a state of marked underreactivity to the environment, accompanied by disturbed motor activity. The syndrome complicates mood disorders, less often schizophrenia, and still less often a variety of neurologic and medical conditions. Consistent with a disturbance in

*The causes are the same for all states: anxiety, stress, paranoia, drugs, and central nervous system damage.
consciousness, patients usually do not clearly remember the episode (Fink and Taylor 2003).

Delirium has as its hallmark waxing and waning of consciousness or acuity of attention. It is caused by any of several adverse influences on cognition (quite often multiple adversities) on the vulnerable person, common among these pharmaceuticals, metabolic derangements, and infections. Those most vulnerable include the demented and the elderly (Inouye 2006). Delirium can superficially mimic many neurological and psychiatric conditions, including stupor.

**Qualitative Changes in Consciousness**

Qualitative changes in consciousness without clear changes in the overall level of alertness occur commonly, and can represent normal or psychopathological functioning (Silverman 1968). These changes are primarily mediated by responses to sensory stimuli and the ability to sustain a focus of attention that causes a partial change in the level of consciousness. For example, a person going to the dentist, if anxious about the experience, is likely to focus considerable attention on the drill, and the experience of pain will probably be intensified. However, if the person attempts to focus attention on music or other distracting stimuli, then pain and discomfort should be diminished. Deliberately shifting the focus of attention underlies many relaxation techniques as well as hypnosis. Consequently, cortical activity can modify sensory input and thereby modify attention, arousal, and anxiety, while anxiety can, in return, modify consciousness.

In psychopathological states, the functions of cognitive input, or sensory and motor functions, are more clearly related to qualitative alterations of consciousness (see Table 34–1). Dissociation has been defined by Spiegel (1994) as, “a separation of mental events that would ordinarily be processed together—a discontinuity of memory, identity, perception, motor function, or consciousness.” Conditions such as dissociative identity disorder, dissociative fugue, hypnotic trance, or conversion disorder would all be classified as partial alterations of consciousness in that one’s consciousness of the body (e.g., people who cannot move their legs) is separated from awareness, but, in general, the rest of the ability to relate to the world is intact. Similar types of splitting of consciousness can be seen with central nervous system damage. Neurologic conditions are very readily confused with dissociative identity disorder (paroxysmal conditions such as epilepsy) and conversion disorder (epilepsy, movement disorders, and loss of neurologic function). Postconcussive amnesia resembles dissociative fugue. Lesions of the nondominant parietal lobe and associated thalamus can produce a “neglect syndrome” or anosognosia, which is somewhat reminiscent of dissociation. This condition has been called “a denial of illness,” although it represents an implicit unawareness of bodily functions or neurologic deficits resulting from the lesion, which may be associated with left hemiparesis. For example, a patient with a paralyzed arm denies that the arm is paralyzed; even when shown the paralyzed arm, the person might deny ownership of the arm (Weinstein and Kahn 1955, Vuilleumier 2004).

Derealization (a sense of detachment from the environment) and depersonalization (a sense of detachment from oneself) are other qualitative changes in consciousness associated with dissociative disorders; indeed, depersonalization disorder is recognized as a distinct disorder in DSM-IV-TR. A sense of numbing or detachment is one diagnostic feature of posttraumatic stress disorder, and is similar to derealization. Arousal and anxiety are related to all of these phenomena, both in terms of related mental disorders and of pathophysiology (Frewen and Lanius 2006, Giesbrecht et al. 2007).

Still other qualitative changes in consciousness include déjà vu (in which the patient experiences a feeling of familiarity in an unfamiliar place) and its converse, jamais vu (in which the patient experiences feelings of unfamiliarity in a familiar place—another phenomenon overlapping with derealization), which may also be associated with increased anxiety levels (Brauer et al. 1970).

Like the level of consciousness, the quality of consciousness can impact on cognitive function. Obviously, that which is experienced (learned) in a state inaccessible to another dissociated state, will not be fully accessible to the person in that other state. This would apply to such uncommon conditions as dissociative fugue and dissociative identity disorder. More generally, the concept of state-dependent learning applies to the less extreme variations in consciousness described earlier, and might detract from cognitive efficiency across these states as well.

**Physiology of Alterations in Consciousness**

Consciousness is traditionally attributed to the brain stem and the reticular structures, but also depends on the coordinated activities of the thalamus, hypothalamus, and basal forebrain, which integrate and relay information to the cortex. Norepinephrine (originating in the locus coeruleus), dopamine (from the ventral tegmentum) and serotonin (from the raphe nuclei) have long been considered important in promoting wakefulness, although the role of serotonin is mixed. Glutamate (widespread), acetylcholine (from the pedunculopontine tegmental nucleus), histamine (from the tuberomammillary nuclei), orexin (from the lateral hypothalamus and perifornical area), and adenosine also promote wakefulness. GABA (from the hypothalamic ventrolateral preoptic nucleus) promotes sleep (Miller and O’Callaghan 2006, Szabadi 2006).

Sleep is an important example of an alteration of consciousness because sleep is really a suspension of consciousness. Sleep shows a clear pattern of cycles and stages when it is studied with electroencephalography. However, sleep differs from coma in that the comatose patient cannot be aroused, and the electroencephalogram in coma fails to show the usual cycles and stages of sleep; the impact of cortical, sensory, and motor inputs is not apparent. General anesthesia via the inhalational gases seems to be mediated by GABA-A receptors and excitatory amino acids (Hameroft 2006).

**Memory**

The man who thinks over his experiences most and weaves them into systematic relations with each other will be the one with the best memory.

**William James**

Memory is perhaps the most recognized and valued aspect of cognition, nearly ubiquitous in mental status assessments and present in some of the earliest intelligence tests (Kramer and Delis 1998). As one could readily imagine, the quality
of our conscious experience would be greatly altered in the absence of memory. Awareness would be fragmented, presumably lacking in the richness of our common conscious experience. Memory is fundamental to all learning and development, including personality and interpersonal relationships (Singer 1995). Memories also provide reference points for our perception of time. Memories are dynamic, providing fitting frameworks for highly individualized views of reality (Tranel and Damasio 1995). Just as memory functions largely outside of conscious awareness (Rugg 1995), we are often less than fully conscious of the extent to which even mild memory deficits can interfere with one’s social and occupational functioning (Squire 1982), and the extent to which nearly all psychotherapies rely on intact learning and memory.

For many patients with brain injury, memory deficits (amnesia) may develop in the absence of other significant cognitive problems (Cohen and Squire 1980, Squire 1987). This has been termed amnestic disorder since the publication of Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III). Retrograde amnesia refers to the inability to recall experiences prior to an event (usually a cortical insult) and is attributed to disruption of the consolidation of memory as a result of this event (Gold 2006). Retrograde amnesia typically evidences a temporal gradient where events closest to the time of trauma are more difficult to recall. Anterograde amnesia refers to the inability to learn new information from the time of brain insult forward. The most common form of amnesia, anterograde amnesia may be partial or complete and has been observed to frequently be a consequence of damage to the medial-temporal and diencephalic brain structures (Milner 2005). Posttraumatic amnesia (PTA) refers to the time period after head injury where consciousness has yet to return to normal and learning new information remains impaired. PTA often includes a time period encompassing both retrograde and dense anterograde amnesia. The duration of PTA in patients recovering from brain injury is often an even stronger predictor of residual neurological dysfunction than duration of coma (Rees 2003). This should also be appreciated that amnesia does not uniformly reflect damage to cortical regions in which memory is processed or stored, as it may emerge as a consequence of damage to the neural system that normally participates in memory formation and storage without itself being a site of storage (Squire 1987). Disruption at any stage of memory can result in amnesia, due to the multiple neural systems involved in memory formation, storage, and retrieval (Rees and Wedding 1994). Indeed, the boundaries between the cognitive effects of direct brain trauma and those of psychological trauma can be uncertain (Rees 2003, Elzinga and Bremner 2002).

Prior to the 20th century, neuropathological studies of patients presenting with Korsakoff’s syndrome helped to first identify the significance of the midline diencephalic regions to amnesia. The famous surgical case of H.M. initially linked the medial-temporal lobes to normal memory functioning. H.M. developed intractable epilepsy, which was surgically addressed by a bilateral anterior temporal pole resection that left him with dense anterograde amnesia without retrograde amnesia (Squire 1987, Milner 2005). This illustrative case focused research attention on anterior temporal lobe structures, the hippocampus and the amygdala, as primary memory sites. We have learned since that unilateral lesions typically result in much milder memory impairment. Many subsequent cases of patients with amnesia due to medial-temporal and other damage, associated with a variety of conditions including trauma, anoxia, arterial occlusions, viral encephalopathies, tumors, and neurodegenerative disorders, significantly advanced our understanding of memory functioning (Rees and Wedding 1994, Strub and Black 1988).

The most influential and misleading subtyping of memory, derived from William James’ 19th century formulation (James 1890), is into short- and long-term. Originally, and technically, short-term memory refers to recall immediately after presentation or during rehearsal; long-term memory refers to recall after any delay, however brief. Recall of information learned years ago is distinguished as remote memory. Confusion arises when “short-term memory” is used to refer to recall after relatively brief delays (Kramer and Delis 1998). For clinical descriptive purposes, memory is often subdivided into three basic types—immediate, recent, and remote—distinguished by the time interval between presentation of the stimuli and retrieval. Immediate memory may refer to the registration of information as a memory trace for several seconds or more, corresponding to both sensory and sometimes short-term memory described earlier. Recent memory assumes some period of memory storage, and might include a person’s recall of day-to-day events, and may refer to information learned hours, days, or even weeks ago. Remote memories typically include memories of events or knowledge learned years ago, usually premorbidly or before a brain injury (Strub and Black 2000).

Natural divisions between various forms of memory may be observed in brain-injured patients. Foremost is the distinction between declarative and nondeclarative memory that is frequently noted in patients with amnesia. Declarative memory is that which can be consciously recollected, such as facts and figures acquired through learning that can be “declared” as knowledge (Rees and Wedding 1994). Declarative memory permits storage of information in association with particular times and places and affords a sense of familiarity about previous events, allowing knowledge bases to be accessed for applications other than those to which learning initially occurred (Cohen and Squire 1980). Declarative memory and new learning are greatly diminished by medial-temporal (hippocampal) damage, whereas nondeclarative and remote memory tend to be spared (Squire 1982).

Declarative memory may be subdivided into semantic and episodic memory, as also reflected in brain injury research. Episodic memory refers to the memory for events that can be placed within a temporal framework or that have happened at a particular time in a person’s life. As such, episodic memory stores the cumulative events in an individual’s life and, in essence, functions as an autobiographical memory. Head-injured patients evidencing medial-temporal lobe dysfunction have often lost recollections of time- and place-specific experiences (Rees and Wedding 1994). In contrast to episodic memory, semantic memory refers to general knowledge or organized information, such as facts, formulas, and vocabulary. Since semantic memory does not refer to particular events in a person’s past, it may remain quite intact, even when episodic memory is impaired.
Nondeclarative memory includes several types of memory, sharing only their lack of usual conscious accessibility. Nondeclarative memory includes sensory–perceptual and motor skills learning (procedural memory) as well as conditioning and priming. These forms of learning are not directly accessible to conscious recollection, retrievable as specific facts, or stored with respect to specific time or place (Reeves and Wedding 1994). Therefore, nondeclarative memory is implicit and tends to be available only by engaging in specific behaviors or cognitive operations and is thus essentially a memory without record. With enough repetition, some declarative memory transforms into procedural memory (a synonym for procedural memory is reflexive memory). Psychodynamic psychotherapy deals in nondeclarative more than declarative memory, for example by working through transference behaviors more than by rendering explicit advice. Numerous case studies of amnestic patients with medial-temporal lobe damage have shown that while they are unable to learn new declarative information, they retain roughly normal procedural learning abilities (Squire 1987). The repeated observation that procedural memory functioning does not demand the same integrity of the medial-temporal regions that is required for declarative memory, demonstrates that procedural memory and declarative memory rely on separate anatomical systems of neural networks. Knowledge is less complete, but these are thought to include the basal ganglia, cerebellum, and motor and sensory cortical areas.

Prospective memory is an additional category of memory functioning that has developed from the cognitive rehabilitation field, and refers to remembering to perform some particular action at a specific future time or place (Figure 34–1). Remembering to turn off the oven after cooking dinner or remembering to bring the necessary change following text.

for memory formation, this memory system also includes several other brain structures. The amygdala integrates different sensory modalities and input from associated structures that receive input from sensory-specific cortical areas and multimodal association areas (Phelps 2004). Extensive afferent and efferent pathways to and from the neocortex converge on the parahippocampal gyrus, providing both hippocampus and amygdala with interconnections to ongoing cortical activity at memory storage sites (Moscovitch et al. 2005). The memory system also includes the mammillary nuclei, which project to the anterior nucleus and receive input from the hippocampal formation through the fornix, and the ventromedial frontal cortex, which receives projections from the anterior nucleus (Moscovitch et al. 2005). Numerous therapeutically relevant or potentially relevant neurotransmitter systems, including acetylcholine, gamma-amino-butyrate (GABA), insulin, angiotensin, and glutamate/AMPA/NMDA mediate and influence memory processes (Amadio et al. 2004).

Memory is uniformly understood as a staged process, but the specific breakdown of stages varies in a confusing manner. The formation of memory may be viewed most basically as involving three stages: (1) acquisition, (2) consolidation, and (3) storage (Squire 1987). Acquisition refers to the input of information from the sensory organs and cortices representing a sensory memory level of storage of brief duration. Consolidation refers to the progressive strengthening of memory traces in order for information to become permanent. Rehearsal and mental elaboration of material may consolidate that information in the short-term memory area of storage and develop a more robust representation of the information. Consolidation of information in short-term memory promotes transfer of the material to long-term memory storage. After transfer to long-term memory storage, information may be further consolidated for the creation of a more enduring memory trace or record (Tranel and Damasio 1995) (Figure 34–2). A somewhat more elaborated model (Kramer and Delis 1998) proceeds from attending, to processing (mental manipulation of the information), to encoding (transforming physical information into a mental representation), to storage. Processing and encoding may be distinct and important processes, as shall be seen in the following text.
In the initial sensory memory stage, where information is first “registered,” the sensory information that is perceived and processed in the primary and secondary sensory areas of the cerebral cortex may remain briefly available immediately after presentation in a sort of neural memory buffer. Sensory memory for visual stimuli or iconic memory may last no more than half a second as a persistence of the visual trace on the retina (Squire 1987). Sensory memory for auditory information, or echoic memory, may persist for up to several seconds in a phonological sensory loop replaying whatever was heard most recently (e.g., phone numbers), if not displaced by new auditory stimuli.

Once sensory memory is registered, the active mental process of focusing on or attending to the information usually involves repetition of the information for retention in short-term memory storage. Sometimes referred to as brief or immediate memory, short-term memory has traditionally been considered to be limited to 7 ± 2 bits of information. Processing (manipulating and analyzing) new information represents a more complex level of short-term memory processing that is commonly referred to as working memory. Information in short-term memory is more likely to be successfully transferred to and retained in the long-term memory stage the more often it is repeated or maintained in short-term memory by elaborative working memory processes such as rehearsal and association (Kramer and Delis 1998). The biological basis of short-term memory has been attributed to sensory-specific neurochemical activation of short synaptic circuits, but this brief pattern of synaptic circuit activation is thought to be easily disrupted by further neurochemical activation resulting from the introduction of new information (Squire 1987).

Recall of information from long-term memory inherently requires the successful progression of information from registration after the sensory memory stage to more persisting elaboration of information in short-term memory storage for consolidation and transfer to long-term memory storage. That information must be transferred back to short-term working memory for recall. Retrieved long-term memory traces may be maintained by association with new short-term memory information and further integrated and synthesized in working memory for further consolidation in long-term memory storage. Long-term memories are not necessarily static memory traces, but rather reflect more of a dynamic record that may be updated and modified to reflect ongoing experience (Kramer and Delis 1998). Memory recall (or recognition) is thought to represent a reactivation and retrieval of knowledge from long-term memory storage to a form accessible to consciousness, as in the recall of specific information or a perceptual motor skill. Functional imaging studies are finding that retrieval of long-term memories also involve the hippocampus and other medial temporal lobe structures (Eldridge et al. 2005, Rekkas and Constable 2005).

Clinical Vignette 1

Ms. A, a married, right-handed, 37-year-old social worker, was evaluated approximately 6 months after an episode of adenovirus encephalitis. The neurological examination was nonfocal and unremarkable. She was oriented to person and place, but not time. She was able to follow two-step commands but not three-step commands. With apparently intact short-term memory, she could complete six digits forward and repeat a four-word list immediately, but she had no recall after 1 min, reflecting severe deficit in delayed memory. She showed pronounced emotional lability, with exaggerated emotional responses, and obsessive thought patterns.

Like many other amnestic patients, she evidenced pronounced retrograde amnesia with impairment on formal tests of new learning ability. She displayed a significant retrograde amnesia of 1 week for events prior to the onset of encephalitis. Although her fund of information, visual–spatial functions, and praxis were intact, she displayed subtle aphasia, reduced verbal comprehension, and severe word-finding difficulties. She was able to sustain her attention for long periods when engaged in familiar activities, but her attentional capacity deteriorated rapidly for complex or unfamiliar demands, particularly, when a new learning component was required, such as following a recipe. Her procedural memory appeared to be well preserved as she was observed to be able to carry out a number of prior learned activities quite competently, such as household chores of laundry, cleaning, and driving in places familiar to her before encephalitis. She exhibited moderate impairment in attempting to learn semantic information and could not recall her previous day’s activities, reflecting episodic memory impairment. Because of her difficulty generalizing or transferring new learning to unfamiliar situations, rehabilitation efforts were conducted (continues)
within her home environment to capitalize on her relatively spared procedural memory. Owing to her semantic and episodic memory deficits, Ms. A was unable to meaningfully participate in psychotherapy. Her family members engaged in family education counseling efforts to better understand her deficits, to learn practical approaches to compensate for her memory problems, and to maintain a predictable schedule and structured environment to minimize Ms. A’s emotional and behavioral dyscontrol.

The biological basis of long-term memory is thought to be a consequence of the synthesis of proteins and RNA in neurons which develops a sequence of molecules encoded with information that are synaptically connected during the time “permanent” learning has occurred (Tranel and Damasio 1995). Molecular changes in a distributed array of neurons correspond to the long-term memory of a life event. In this fashion, the molecular consolidation of long-term memory is thought to create a relatively stable record of information. Functional imaging reveals that encoding into long-term memory involves the hippocampus and association cortex (Otten et al. 2002, Eldridge et al. 2005, Kong et al. 2006). Once long-term memory storage has been completed, the successful recall of that information involves entirely different processes. While the capacity of long-term memory storage is vast, memories in long-term storage are vulnerable to decay and susceptible to distortion, as in the cases of delusional memories and false memories (Loftus 1980).

In working memory, one or more multiple sources of information are temporarily maintained and manipulated in an on-line fashion for periods of several seconds. Since the integration of information in working memory involves a synthesis of many subtasks such as organizing, monitoring, planning, and selecting information, working memory is highly dependent on the integrity of the prefrontal cortex. Since memory dysfunction due to frontal lobe pathology tends to be more associated with deficits in regulating attention and organizing or sequencing information, such working memory disturbance has been referred to as executive memory dysfunction (Shimamura et al. 1991). On detailed psychometric assessment of memory functioning, frontal lobe or executive memory dysfunction is usually distinguishable from memory disorders resulting from damage to the diencephalic midline or the medial-temporal regions, although this distinction may require detailed testing to clarify. Consistent evidence now indicates that the dorsolateral prefrontal cortex participates in retrieval of long-term memory (Gilboa 2004, Sakai 2003), and may serve an executive role in organizing memory resources (Rypma 2006).

**Intelligence**

We should take care not to make the intellect our god; it has, of course, powerful muscles, but no personality.

Albert Einstein

One of the most important factors determining how a person negotiates or knows the world is the capacity for learning, reasoning, and understanding summarized by the term intelligence. While many different forms of intelligence may be theorized and measured in some fashion such as social, musical, and emotional intelligence, our focus of interest is measurement of the intellect’s higher mental capacities for acquiring, understanding, and manipulating knowledge. Early intelligence quotient (IQ) expert David Wechsler believed that intelligence could be determined by the sum of many different specific abilities, and defined intelligence as “an aggregate or global capacity of an individual to act purposefully, to think rationally, and to deal effectively with his/her environment” (Wechsler 1944). Exactly which cognitive skills and abilities provide reliable and valid measures of intelligence has been an issue of considerable controversy over the past century, with numerous theoretical models of intelligence proposed. Over 30 years ago, Tranel et al. (1973) offered a multimodal model of intelligence that still conceptually parallels the modern-day assessment of intellectual functioning. They defined three key areas of intelligence: (1) abstract or verbal intelligence concerns the ability to use symbols; (2) practical intelligence, the facility to manipulate objects; and (3) social intelligence, the facility to deal with human beings.

The origins of modern-day intelligence tests date to efforts in France (Binet and Simon 1905) and, subsequently, in the United States to develop standardized intelligence tests for identification of children in public school systems with learning and intellectual disabilities. The goal in those days was not much different than it is today, to provide improved curricula and remedial teaching for developmentally delayed and other special needs students. With World War I, a need for the US military to evaluate new recruits and select officers for training prompted the development of group-administered intelligence tests assessing verbal and nonverbal (visual) abilities, called the Army Alpha and Army Beta Tests, respectively (Anastasi and Urbina 1997). After working as an Army intelligence examiner, David Wechsler developed the first in a series of individually administered IQ tests called the Wechsler–Bellevue Intelligence Scale, that gave equal weight to both verbal and visual abilities in determining overall intelligence (Wechsler 1944). Separately measuring various verbal and visual abilities, the subtests were combined to determine an individual’s Verbal IQ separate from the visual or Performance IQ, before both were merged for an overall Full-Scale IQ. This distinction between verbal and performance cognitive abilities has proved over the years to be the most pragmatic approach to evaluating intelligence for most purposes. In addition, the Wechsler Scale’s approach of generating deviation IQs based on standard scores—rather than on the MA/CA (mental age divided by chronological age) formula that had been used previously to compute IQs—has helped to establish the various Wechsler Intelligence Scales that have been standardized for preschoolers, children, adolescents, and adults as the gold standard measures of intelligence (Kaufman and Lichtenberger 1999). Global measures of intelligence like the Wechsler Full-Scale IQ (FSIQ) serve as the foundation for numerous state laws determining service eligibility for both children and adults. Individual IQ assessment is a basic requirement to determine qualification for social security disability. In many areas of life, a global IQ score such as the FSIQ is often regarded as representing the most general estimate of a person’s ability, against which other measures
of ability, specialized skills, or traits are compared (Tulsky et al. 2001).

The reasons for intelligence testing today are many, but, in clinical practice, usually have to do with evaluating cognitive impairment or decline in neuropsychiatric disorder. For the physician, information derived from the clinical psychologist’s interpretation of Wechsler Adult Intelligence Scale III (WAIS-III) test results may be invaluable in helping to identify disorders usually first diagnosed in childhood or adolescence and to help determine diagnoses of dementia, amnestic, and other cognitive disorders. Intelligence assessment alone for patients with such known or suspected disorders is inadequate to evaluate the full range of cognitive strengths and limitations a patient may exhibit. It is generally necessary to evaluate multiple areas of cognitive ability with a neuropsychological evaluation. Integration of IQ results with findings from these other tests—which might cover attention, language, academic functioning, immediate and delayed verbal and memory, visual–spatial problem solving, motor and sensory–perceptual functioning, executive functions, and emotional functioning—is crucial to place these other findings in a context of overall intellectual ability, which is essential for treatment planning (Anastasi and Urbina 1997).

The design of the Wechsler Intelligence Scales involves the use of multiple subtests summing up to two equally weighted intelligence summary scores representing verbal and visual–spatial functions. Thus, there are three IQ scores or indexes: Verbal Intellectual Functioning (VIQ), Performance Intellectual Functioning (PIQ), and overall Intellectual Functioning or Full-Scale IQ (FSIQ). The three IQ scores are standardized to have a mean of 100 and a standard deviation of 15 (Wechsler 1997). Accordingly, two-thirds of the population in the United States would be expected to have a FSIQ between 85 and 115. Nearly 95% of the population score within 2 standard deviations of 100 or have IQs between 70 and 130. Demonstration of overall intellectual functioning below 70 roughly corresponds to a diagnosis of mental retardation.

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV-TR) (American Psychiatric Association 2000), requires concurrent deficits or impairment in adaptive functioning in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety, and an IQ below around 70 for a diagnosis of mental retardation. Mild retardation generally corresponds to a FSIQ range from 50–55 to approximately 69. Moderate mental retardation reflects IQ levels from 35–40 to 50–55; severe mental retardation corresponds to IQ levels from 20–25 to 35–40; and profound mental retardation is designated for IQ levels below 20–25. IQs between 70 and 79 are classified as borderline mental retardation, IQs between 80 and 89 are low average and IQs between 90 and 109 are considered to be in the average range. High average IQs are between 110 and 119 while superior range IQs correspond to scores between 120 and 129. A very superior level of intelligence (FSIQ 130 and above) in conjunction with demonstration of exceptional abilities in other areas is the standard for “giftedness.” The WAIS-III ceiling for reliable FSIQ measurement of 155, which some would classify as genius range, is over 3.5 standard deviations above the mean. The WAIS-III is, thus, capable of identifying individuals with exceptional intellectual abilities.

Numerous intelligence tests have been developed in recent decades, but the WAIS IQ tests remain the standard and most widely used instruments for the clinical assessment of intelligence between the ages of 16 and 89 (Wechsler 1997). Wechsler’s distinction in the late 1930s between verbal and visual abilities also proved enduring, and compatible with subsequent studies of brain functioning. Many investigations supported associations between left-hemisphere functions and VIQ subtest performances, and between right hemisphere visual–spatial functions and PIQ subtest performances. The multiple subtest profile design of the Wechsler scales, which allows assessment of significant discrepancies between verbal and visual–spatial cognitive ability, has been most important to our still-emerging understanding of verbal and nonverbal learning disabilities.

The WAIS-III national standardization sample (N = 2450) was stratified according to age, sex, race/ethnicity, geographic region, and level of education on the basis of distributions from the 1995 US census data (Wechsler 1997). This normative sample consisted of persons distributed across 13 age groups with 100–200 subjects per group between the youngest group (ages 16–17) and oldest group (ages 85–89). The WAIS-III consists of 14 subtests with seven measuring verbal and seven assessing visual–spatial abilities (Table 34-4). The Verbal IQ scale is composed of the subtests: information, digit span, vocabulary, arithmetic, comprehension, similarities, and letter-number sequencing. The visual–spatial or Performance IQ index consists of subtests: picture completion, picture arrangement, block design, matrix reasoning, symbol search, object assembly, and digit symbol. Each of these 14 subtests yield a separate subtest scale score with a mean of 10 and a standard deviation of 3. To some extent, each subtest measures a relatively

distinct cognitive ability or skill with a proportion of variance unique to itself. Each subtest also shares interrelated abilities and a common variance with other verbal and visual subtests requiring knowledge of subtest error-variances and specificity for IQ profile interpretation (Kaufman and Lichtenberger 1999).

The WAIS-III’s major enhancement or structural change from the previous Wechsler adult test of intelligence, the Wechsler Adult Intelligence Scale (Revised) (WAIS-R), was the addition of four new factor analytically derived index scores, in addition to the traditional VIQ, PIQ, and FSIQ index scores. Based on scores from 11 of the 14 IQ subtests, the two new verbal ability indexes are called the Verbal Comprehension Index, incorporating word and factual knowledge with verbal reasoning, comprehension, and expression, and the Working Memory Index, reflecting the ability to hold information in mind while manipulating that information. The two new visually oriented indices are the Perceptual Organization Index, measuring visual–spatial integration, reasoning and problem solving, and visual–motor construction ability, and the Processing Speed Index, including speed of visual processing, problem solving, and perceptual motor speed. Applying these alternate indexes to IQ interpretation can increase the understanding of a patient’s cognitive ability structure and reliably identify when significant discrepancies exist between indices. In situations where extreme variability exists between the IQ indexes or factors making up the FSIQ, the FSIQs may no longer reflect a unitary construct and, therefore, may not be interpreted reliably (Kaufman and Lichtenberger 1999). In order to calculate the new index scores and a patient’s VIQ, PIQ, and FSIQ index scores, though, a full WAIS-III test administration requires nearly 2 hours.

Some verbal subtests evaluate what are traditionally regarded as “fluid” cognitive abilities involving attention, concentration, and working memory, which tend to be highly sensitive to brain injury, as well as the attention–memory and other cognitive disturbances associated with acute psychiatric disorders. Examples of this are the similarities and arithmetic subtests. Other subtests, such as information and vocabulary, evaluate more stable cognitive abilities. These subtests are thought to evaluate information in long-term memory storage such as language and academic skills and abilities (Larrabee et al. 1985). These overlearned abilities are often referred to as “crystallized” cognitive abilities. Consistent with expectations from the diffuse cortical distribution of long-term memory storage, crystallized cognitive abilities are less sensitive to brain injury than the “fluid” abilities. Although these “hold” subtests are often reported as estimates of premorbid intellectual ability, they may also evidence decline in advanced or severe neuropsychiatric disorders such as global dementia.

Where reliable premorbid IQ results are not available, intellectual assessments are relatively insensitive to frontal lobe-associated cognitive dysfunction. Subtests that measure “fluid” cognitive abilities, such as the Digit Span subtest, tend to be more adversely affected by frontal lobe pathology, but the declines may be too subtle to reliably detect by IQ assessment alone. Verbal intellectual functioning, in general, is strongly associated with level of education, so that more years of education tends to increases one’s measured Verbal IQ. The performance subtests, in general, evaluate the ability to solve novel visual–spatial problems and are less dependent on formal schooling than verbal subtests. These visually mediated subtests are usually more susceptible to decline in cases of acute psychiatric disorders, head injury, or other cases of generalized and diffuse cognitive dysfunction, such as most of the degenerative dementias (Anastasi and Urbina 1997).

Due to the standard error of measurement, IQ scores and indexes are not regarded as precise quantitative measures. They are more accurately considered to reflect a level or range of intelligence within which the patient is functioning. Whether the clinical goal of IQ assessment is to aid differential diagnosis or to determine whether a patient’s intellectual abilities have declined, the standard error of measurement is always an important interpretative consideration. Controlled standardized test administration procedures are also required for reliable assessment of a patient’s intellectual functioning to allow valid interpretation of the results. As with any assessment of a patient’s cognitive functioning, numerous factors may affect measured levels of IQ functioning, including poor rapport with the examiner, lack of effort and motivation, medical and psychiatric conditions that compromise attention and memory capacity, sensorimotor limitations, and especially language and cultural discrepancies from the standardization sample. Computerized printouts of intellectual test results do not take such factors into account. Usually, the expertise of a psychologist with training in psychological assessment is necessary for reliable interpretation of IQ and neuropsychological test results. Accurate clinical diagnosis frequently requires the convergence of findings from many specialties, and reliable interpretation of intellectual or neuropsychological test results is important for integration with neurological, radiological, and psychiatric findings. Competent interpretation of IQ findings should incorporate (1) the patient’s current level of verbal, visual, and overall intellectual functioning and the validity and reliability of the IQ test results, (2) comparison of a patient’s current IQ functioning to normative or appropriate clinical samples and measures of premorbid functioning, (3) significant differentials between IQ indexes and subtest scores to illustrate cognitive deficits and strengths or preserved areas of cognitive functioning, (4) multiaxial diagnoses, and (5) any limitations of the database.

Clinical Evaluation
The cognitive evaluation is highly important in identifying reversible medical and neurological causes for psychiatric disturbances. The central nervous system has only a limited number of responses to any type of disturbance, so identical symptoms evident on mental status exam may be due to a variety of causes (Table 34–5). For example, a dementia syndrome could well be due to depression, a toxic exposure, head trauma, tumor, seizure disorder, encephalitis, or, even, a severe stressor.

Thus, the longitudinal history of the syndrome is often key to differentiating its cause. Most dementias do not manifest themselves as abrupt changes in personality and behavior, rather developing over months to years. With the current emphasis on specific diagnostic criteria, one is sometimes inclined to think the diagnostic task is done when the patient’s current symptoms fit DSM-IV-TR criteria. However, this reflects the patient’s symptoms only at one point in time.

Although it has its limitations, the cross-sectional profile of behaviors and abilities does have diagnostic value. It can suggest a medical etiology, especially if the presentation is atypical for dementia or amnestic disorder, and particularly, if the cognitive examination is dominated by inattention and disorientation (signs of delirium). The cross-sectional picture can also point to a psychological origin (pseudodementia in the context of depression and/or anxiety) when the patient complains of cognitive difficulties, highlights failures, and shows inconsistent performance across different modalities. The opposite is often the case in early stages of dementia: patients tend if anything to deny and conceal their deficits.

Evaluation of Orientation

The changes in orientation most often seen in central nervous system dysfunction relate to knowing time, place, and person. The sequence of the loss of these functions often correlates with the severity of insult to the brain (Table 34–6). For example, orientation to time is generally the first function lost and usually indicates early or mild damage. In light of the diagnostic significance of orientation to time, the Mini-Mental State Examination explores time orientation by requesting the patient to provide day of the week, month, date, year, and season (Folstein et al. 1975). Orientation to place is often lost next; one often sees large signs with such patients’ names identifying their rooms. Disorientation to self is uncommon in a fully conscious and coherent person. Orientation testing can be unreliable, as chronically disoriented patients may learn compensation techniques.

Evaluation of Memory

Like all assessments of a patient’s cognitive functioning, valid memory test results are contingent on adequate attention, motivation, and patient effort. Memory dysfunction associated with neuropsychiatric disorder is, therefore, easily misdiagnosed, resulting in inappropriate and costly interventions. Depression or anxiety can result in reduced effort and motivation confounding memory evaluation, and severe depression may induce deficits in attention and memory for some patients. Subclinical depressive disorders may present with complaints of memory or other cognitive difficulty, but, typically, do not show objective evidence of memory impairment on formal testing. The detection of cognitive deficits secondary to depression in patients with clinically significant depression will usually require more detailed psychometric memory testing than is typically afforded by the memory assessment of a brief mental status exam. Complaints of memory dysfunction tend to be more prominent in patients with acute as opposed to recurrent or chronic depression and the extent of “actual” memory impairment secondary to depression can vary widely (Strub and Black 2000). For some patients with major depression, their complaints about difficulty with memory, attention, and other cognitive functioning may offer an avenue for expression of emotional distress, serving as an alternative to somatic complaints. Complaints of memory difficulty in depressed patients have been demonstrated to be highly correlated with the severity of depression but unrelated to actual impairment in objective measurement of memory functioning. Antidepressant treatment that significantly improved depressive symptoms in patients with major depression was conversely associated with a significant decrease in patient complaints of memory problems (Claypoole et al. 1998).

When evaluating a patient for memory deficits associated with dementia, identification of the etiology is always crucial to determine whether the cognitive impairments may be reversible. If appropriate treatments improve dementia symptoms and memory impairments, it is important to determine the persistence of cognitive impairment following treatment. The differential diagnosis between depression

and dementia may be clinically challenging, particularly, for those patients who are in the early stages of decline (Nussbaum 1994). The onset of depression, especially for patients without premorbid psychiatric history, may be primary to both the neuropathological process and/or secondary to the patient’s perceived loss of functioning. Treating depression in these patients may temporarily improve memory along with other cognitive functions, yet it is difficult to cancel out the adverse memory effects of depression from those of dementia. Effortful and demanding memory tasks have been shown to be differentially impaired in patients with depression, while dementia patients typically exhibit impairments in both effortful and automatic memory processing tasks (Nussbaum 1994). Longitudinal evaluation of a patient’s memory functioning is usually required to address the complex interactions between the effects of depression and dementia on memory functioning, particularly, as late-life depression without cognitive impairment can be a harbinger of dementia (Baldwin et al. 2006, Brodaty et al. 2003).

Basic memory functions are relatively easy to evaluate clinically. Assessment should involve short-term auditory memory and brief attention span provided by digit span repetition tasks (registration), verbal learning capacity, and efficiency of recall of recently learned verbal and visual information after a brief delay. Long-term memory may be evaluated by recall for remote personal history (episodic memory) and historical facts (semantic memory). A good deal of information can be learned about a patient’s memory from tests of learning capacity that offer a learning curve, and from the linear and sequential or disorganized way in which the patient relates his or her life history. This may require confirmation by others. The ability to recall numbers forward and backward, like the Digit Span subtest of the WAIS-III, is usually the standard test of short-term (immediate) auditory memory, and also demonstrates adequate registration. Most adults should be able to repeat at least six numbers forward and five backward. This ability may decrease slightly with age, and most patients should be given at least two trials. It is also important to start out slowly by asking patients to remember and repeat only two or three numbers before progressing to larger strings of numbers. Amnestic patients may exhibit normal performance on forward digit span due to intact sensory memory, but will tend to exhibit impairments with the more challenging backward digit span trials that challenge working memory. Remote memory is reflected by the temporal sequence and order in which the patient conveys past information, but information is best confirmed by others. There are some patients who tend to confabulate (fill in memory deficits with material that they create to hide these deficits). A simple test to check for confabulation is to ask the patient, “Have you seen me before?” Frequently, patients who confabulate will assure you that they have met you and will talk about where and when this took place.

Dissociated states and amnestic conditions also present a difficult problem in differential diagnosis. Most often, amnesia due to brain damage is patchy, with little pattern to gaps beyond a possible temporal gradient, or it can be total for brief historical periods in the patient’s life, as in transient global amnesia (Quinette et al. 2006). Fugue states or psychogenic amnesia usually relate to traumatic or psychosocial precipitants and have a sudden onset in the absence of organic disorder; often, there is some gain to the individual for not remembering (e.g., to manage guilt, it is to her or his advantage not to remember). Frequently testing the patient’s knowledge in a number of different areas can clarify the dissociative or “functional” nature of an amnestic complaint; for example, when a patient claims to have complete amnesia from birth on, but can, often, still perform various mathematical functions, and name the months of the year. Neuropsychological testing may be necessary to clarify memory and other cognitive difficulties that screen positive on the screening cognitive examination.

Evaluation of Judgment and Insight

Mental status examinations also involve estimates of judgment and insight. Direct questions about judgment attempt to determine whether the patient is aware of what normal, social interaction or responses are. For example, a frequently asked question is, “What should you do if you are in a theater and notice a fire?” Alternatives might be, “Why are laws necessary?” or “Why should people stay away from bad company?” Such questions serve the stated purpose, but superficially, and with uncertain relevance to the real world. Judgment must be examined in the context of recent behavior, the patient’s intelligence, memory, and the integrity of other cognitive functions; diagnosis and treatment adherence. A patient may have the sense to quietly exit the hypothetical burning theater, but relate a personal history replete with examples of very poor choices.

Insight may be measured in terms of the patient’s understanding of his or her condition and need for treatment. There are many facets of insight, including the presence or absence of a problem, the presence or absence of a personal (as opposed to environmental) problem, of a mental or psychological (as opposed to purely physical) problem, regarding the particular type of psychological problem (e.g., a psychotic patient may argue that the problem is only stress), regarding the need for treatment or the specific type of treatment (inpatient or outpatient, antipsychotic medication or antibiotic), etc. The term lack of insight is occasionally overused; the clinician should avoid concluding that the patient lacks insight, when it might be reasonable for the patient (or even another clinician) to disagree. In either event, the patient’s view of the problem, whether insight or not, is critical, as it largely dictates the physician’s approach to treatment.

Conclusion

The biologically and psychologically interdependent functions of consciousness, orientation, and memory are the primary aspects of how we appreciate and negotiate life. They are so basic and central to our lives that we often take them for granted because in most cases they function automatically. However, their separate evaluation is critical for each patient because they are sensitive indicators of how the central nervous system is functioning and of the current and future capacities of the patient to function independently.

CHAPTER 35

No laboratory test has yet been developed that defines or determines the severity of any psychiatric disorder. Neither is there a laboratory probe that characterizes the content of an individual’s thoughts. Instead, these determinations are based to a large extent on the verbal productions of patients. The routine psychiatric “laboratory” thus exists as interactions between psychiatrist and patient primarily, although not exclusively conversational in nature, designed to elicit characteristic signs and symptoms. Some principles of psychiatric phenomenology may be worth making explicit to put this unique interview process in perspective.

First, psychiatric disorders do not intrude on all realms of brain or cognitive function equally. To quote Hughlings Jackson (1932): "In every insanity there is morbid affection of more or less of the highest cerebral centres or, synonymously, of the highest level of evolution of the cerebral sub-system. . . ." In other words, it is precisely our advanced and most developed faculties, those faculties that define us as human and as individuals, which are altered by psychiatric conditions. These include a person’s willfulness, the rich tapestry of emotions directing that willfulness, the ability to know and judge one’s own behavior and that of others, and the ability to express in words complex ideas, including ideas about how one experiences oneself and one’s own mental processes. These domains, by virtue of their complexity, are often difficult to objectify.

Second, these higher level processes are integrative; consciousness examined, therefore, via a psychiatric interview does not cleave readily along the traditional subdivisions of mental capacity, that is, perception, belief, emotion, thought, and language. Each of these domains informs, guides, and constrains the others. Given that psychiatric disorders involve higher level mental processes, it is the rule rather than the exception that a psychiatric disorder in a particular person will also cut across different higher level capacities, producing alterations that interweave language, belief, thought, perception, and emotion. Recognizing how these different capacities are realigned with respect to each other—rather than identifying an impairment within a single domain—offers the most informative phenomenological approach to the patient.

Third, contextual factors that shape personal beliefs, expectations, and behaviors must always be attended to. These factors include personal and family history, cultural background, and current circumstances. All too often we are left having to make difficult distinctions between the boundary of normalcy and pathological conditions when such information becomes critical. When does healthy vigilance in a dangerous environment cross over to paranoia? When does mourning the loss of a loved one become a morbid preoccupation? Under what settings might a loose association, in fact, really be a poetic turn of phrase? When is experiencing an angelic presence a predictable outcome of religious worship rather than a delusion? Along these lines, it should be kept in mind that psychiatric manifestations fall along a continuum, ranging from normal variants to the most extreme cases (Strauss 1969). The presence of intermediate phenomena, which, in isolation, are not readily classified as either pathological or normal, has been clearly documented (Strauss 1969).

With these caveats in mind, we shall attempt to characterize major aspects of psychiatric phenomenology.

Disorders of Speech

Patients produce a range of speech behaviors that have clinical significance. Central to this discussion is the concept of formal thought disorder. This term unfortunately ignores the linguistic nature of deviant discourse but has heuristic value insofar as it implies that such deviance reflects how ideas...
flow from one to another during the course of speaking rather than the specific content of ideas themselves.

The *sine qua non* of formal thought disorder is “looseness of association” or “derailment.” These terms refer to speech that the psychiatrist cannot “follow,” that is, where the overall intention or point of the utterance becomes lost as the speaker shifts idiosyncratically from one frame of reference to another (Andreasen 1979). Consider the following example taken from Hoffman et al. (1982):

**Interviewer:** Tell me about where you live.

**Patient:** I live in one place and then another place. They’re black and white you know. That’s why I love Christmas and stuff because, you know, it’s different colors. I used to live in Brooklyn.

Here the patient seems to be responding to the interviewer’s prompt but switches to a Christmas motif that fails to elaborate on or remain attentive to a particular frame of reference. In contrast, looseness of reference to another (Andreasen 1979). Consider the following example:

**Interviewer:** Did you ever try to hurt yourself?

**Patient:** I cut myself once when I was in the kitchen trying to please David. I was scared for life because if David didn’t want me then no man would.

Here the patient seems to be talking about two frames of reference, the first pertaining to cutting herself, presumably while preparing food, and the second pertaining to reasons for being suicidal. The shift is without warning, that is, the patient did not help the listener by saying, “I never intentionally hurt myself but I was so upset about David that . . .”

Another related type of discourse production deviance is “flight of ideas.” Some authors have not distinguished flight of ideas from derailment (Andreasen 1979), but there is some empirical evidence that the two terms can refer to similar but distinct phenomena (Hoffman et al. 1986). Flight of ideas also refers to speech with shifts in frame of reference, but when the shifts in frame of reference are less idiosyncratic. At times, such shifts can be instigated by similarity of sound of particular words rather than topical relationships (clang association). Most important, the speaker seems to retain the ability to flesh out particular themes or topics when he or she is able to remain within a particular frame of reference. In contrast, looseness of association suggests a sustained inability to fully and coherently elaborate on or remain attentive to any theme or topic. Flight of ideas is associated with mania and various medical conditions or substance-induced psychotic states (e.g., thyrotoxicosis, amphetamine-induced psychosis). This form of thought disorder is typically accompanied by pressured speech, that is, speech produced at an abnormally rapid rate that is difficult to interrupt (Andreasen 1979).

A less severe type of formal thought disorder is referred to as “tangentiality.” Here, the shifts in frame of reference are less abrupt and, at any particular time, the speaker seems to offer a coherent message. Over time, however, the speaker clearly strays from the original frame of reference. For example:

**Interviewer:** Can you tell me where you live?

**Patient:** I live in Connecticut. We live in a 50-year-old Tudor house that is very much a home. The house shows my personality. It is comfortable and modest. My husband’s personality is very different. He is a very closed-off person who makes people feel ill at ease.

An even milder form of formal thought disorder is “circumstantiality,” sometimes referred to as “digressive speech.” Here, the shifts in frame of reference occur, but the speaker is able to return to the original conversational point:

**Interviewer:** What are your thoughts about politics?

**Patient:** Well, I’m most interested in national politics, you know, what the President is doing. I think that a lot of our problems are up to him to solve. But I don’t know then again if any human being can pull off what he’s gotta do. People always promise more than they deliver. That’s been my experience all along, teachers, bosses, parents. My life is just one disappointment followed by the next. It gettin’ so that I just expect the worst. And that’s probably gonna be the case with our new President.

Formal thought disorder, if prominent, is generally associated with the more severe psychiatric illnesses (e.g., schizophrenia, bipolar disorder, psychotic or mood disorders that are due to general medical conditions or that are substance induced) but does not occur inevitably in these conditions. Milder examples of formal thought disorder are frequently seen in patients with a range of diagnoses, including major depressive disorder, schizotypal personality disorder, and cyclothymic disorder.

Of note is that each of the segments just discussed does not demonstrate any intrinsic alterations in inferential reasoning. Instead, difficulties reflect the flow of sentences and the degree that each coheres to a common theme or topic. Actual breakdowns in reasoning are referred to as illogical thinking. A now classic example was cited by Arieti (1974):

*I am a virgin.*

*The Virgin Mary is a virgin.*

*Therefore I am the Virgin Mary.*

Perseveration reflects the repeated use of particular words or phrases. It is commonly seen in patients with memory impairments resulting from dementia or lesions involving the hippocampal system, and less often in patients with schizophrenia.

Another speech impairment is defined by reduced conversational output and is referred to as poverty of speech. Spontaneous speech is markedly diminished or absent, and responses to questions are met with replies consisting of only a few words. Poverty of speech, or alogia, can be seen in schizophrenia and depression. Patients with anterior aphasia also demonstrate poverty of speech because of impairment in the motor areas of the brain dedicated to speech production. Patients with so-called fluent aphasia (associated with posterior lesions) can also demonstrate poverty of speech during their recovery process; it is likely that these patients curtail their speech production as they become increasingly aware of its intrinsic disorganization. Extreme poverty of speech is
known as *mutism* and can be seen in schizophrenia, disassociative disturbances, catatonic syndromes, and a wide range of brain lesions. Catatonic syndromes are also associated with echolalia, in which the speaker automatically reproduces words or phrases uttered by the interviewer. Thought blocking is extreme poverty of speech that occurs episodically. Patients with this symptom report either that their minds “just go blank” or they are flooded with racing thoughts and cannot sort out a particular message to articulate. Thought blocking is often accompanied by considerable anxiety, which often worsens this symptom. When the patient perseverates on the same word, phrase, or theme, especially if the patient is vague or elliptical, poverty of content of speech can occur even if a normal amount of speech is produced. Poverty of content of speech is most closely associated with schizophrenia and various aphasic syndromes.

Concrete speech involves the use of literal meaning. Verbalizing in conceptually abstract contextual frames is absent, as is the ability to use metaphor:

**Question:** What happened recently that brought you into the hospital?
**Answer:** A taxi came.

At times, patients produce “lower level” impairments in word construction and selection and in sentence syntax, which provide important clinical information. Consider, for instance, the following utterances:

- he is a *grassical* person
  (Hoffman and Sledge 1984)
- he still had *fooch* with **teykrimez**,
  I’ll be willing to betcha
  (Chaika 1974)

These nonwords are characteristic of patients with aphasia caused by impairment of dominant cerebral hemisphere speech centers but can also be produced sporadically by patients with severe schizophrenia.

Another type of lexical deviance occurring in schizophrenic and aphasic speech reflects words inappropriately combined with grammatical endings or other words:

- attain *vigoration* and strength
  (Hoffman and Sledge 1984)
- stated not necessarily *factuated*
  (Vetter 1968)
- that’s a lie-truth
  (Bleuler 1950)

Slips of the tongue are nonwords that reflect the exchange of phonemes within a phrase:

- *soul hecond* path (intended: whole second path)
  (Chaika 1974)
- or the fusion of words within a phrase:
  - *a prettiotic* idea (intended: a pretty idiotic idea)
    (Fromkin 1975)

In general, spontaneously produced nonwords that are not slips of the tongue are referred to as neologisms in the psychiatric literature and paraphasias in the neurology literature.

Patients can also demonstrate word-finding problems that result in inappropriate insertion of lexical elements into sentences. A “mild” example is

He owns a store on Fifth Avenue, and that’s never mentioned because that is his side-kick *(intended: side-line).*

(Hoffman and Sledge 1988)

An example of a more severe error in word selection corresponds to a noun inappropriately inserted into a verb-slot of sentence structure:

- *fish school* in their own communities
  (Hoffman and Sledge 1988)

Psychotic and aphasic patients, moreover, may also produce paragrammatisms, that is, utterances in which word order or word combinations deviate from acceptable syntactic forms. An example (which also includes a paraphasia) that still expresses the remnants of grammatical structure follows:

- *That’s why, you know, the fact there was no stigmatism (sic) attached to that clearly explained in the record why you were put back.*
  (Hoffman and Sledge 1984)

More deviant utterances of this type are referred to as word salad or incoherence:

- The honest bring-back-to-life doctors agents must take John Black out through making up design meaning straight neutral underworld shadow tunnel.
  (Chaika 1974)

Severely psychotic patients may produce sporadic neologistic or paragrammatical constructions. Prolonged social isolation or sustained alienation from other human beings, coupled with bizarre ideation, may, over time, lead the schizophrenic patient to disregard the constraints of ordinary language. If persistently expressed during most utterances, such deviance is much more likely to be produced by patients with aphasia caused by a lesion of the dominant hemisphere (Lecours and Vanier-Clement 1976). Patients with temporal lobe epilepsy may, at times, produce mild, episodic word generation difficulties and paragrammatisms, but these generally occur in the absence of formal thought disorder, as defined earlier.

With stuttering, there is a clear interruption of the flow, rhythm, and completeness of syllables, words, and phrases, but meaning and context are unaffected. Speech is spasmatic and uncoordinated, and, like other dysarthrias, appears related to problems in the muscular coordination.

Finally, it should be noted that most of us are far from perfect speakers. Slips of the tongue, errors in word selection, garbled words, tangentiality, and even frank looseness of associations can be produced sporadically by normal individuals, especially under conditions of heightened arousal or fatigue. Therefore, an important aspect of speech behavior is self-monitoring and subsequent correction of momentary speech irregularities. A failure to recognize and correct
one’s own speech irregularities may be an important clue that a significant pathological condition is being expressed. Table 35–1 summarizes disorders of speech.

Disorders of Thought
First, a simple observation. Many psychiatric disorders present with repetitive mental content, and almost all psychiatric disorders impose some curtailment on content variance. Consider, for instance, the psychotic person who harbors false beliefs that are invulnerable to invalidation even if the patient is presented with overwhelming evidence to the contrary. For instance, a delusional patient will believe that her room is bugged even after the room has been completely torn apart looking for the bug.

In contrast, obsessions are preoccupations that the patient is able to acknowledge as being irrationally based. Compulsions are repetitive actions due to obsessions. There are a number of fairly typical obsessions, including a preoccupation with dirt, contamination, or disease, which may be accompanied by ritualized behavior such as repeated hand washing. Repetitive checking is another typical obsessive syndrome, in which the individual is preoccupied with and repeatedly attempts to correct certain potentially dangerous situations (e.g., stoves or irons left on, leaving doors unlocked). Repeated verification of the fact that no such risk exists only temporarily alleviates the anxiety associated with the preoccupation. It is as if the patient cannot retain the memory that the front door was checked minutes earlier. Checking is often conducted in a ritualized fashion, for instance, by repeating the check a predetermined number of times while repeating the Lord’s Prayer. A third common syndrome is obsessional orderliness. Here, certain objects need to be arranged in precise order, at times to an absurd degree. Obsessions are generally associated with anxiety and the expectation that terrible consequences will occur (e.g., the house will burn down, the family will be killed) if ritualized behaviors are not completed. Even though the patient will acknowledge that these preoccupations are not rationally based, they can come to dominate his or her entire life. These preoccupations are future-oriented. Patients are condemned to ask themselves repeatedly, “What can I do to avert future disaster?”

Ruminations generally have a basis in a true past experience of the patient. A typical example is a preoccupation with the loss or betrayal of a loved one. Ruminations, in general, are concerned with the irreversibility of certain past events and are associated with affects such as remorse and sadness. When severe, obsessions and ruminations can assume psychotic proportions. In other words, the patient’s awareness of the irrationality of the preoccupation is lost. Persistent compulsions can evolve into belief, as illustrated in the following vignette.

Clinical Vignette 1

A 19-year-old man had a long-standing compulsion to pick up trash on the street and endlessly sort through this collection at home. The elusive nature of “insight” was particularly striking in this patient. Although he found these habits disturbing and attempted to resist them, over time he began to express the conviction that these activities were his “special mission” in life and, later, that the objects were commanding him to perform the rituals.

Delusions commonly invoke “unseen” forces or processes (aliens, secret agents, microelectronics, the devil)
because they de facto are difficult or impossible to verify by direct experience. This contributes to the irrefutability of the delusion. A more subtle example of this same phenomenon (in this case accompanied by a clinical depression) is as follows:

Clinical Vignette 2

A 38-year-old woman read in the newspaper that an automobile accident resulting in the death of a boy occurred on a country road near her home. She determined that she had driven down that road the same night, although she could not recall seeing the boy. Nonetheless, she became convinced that she killed him. Police reports and the absence of any telltale damage to her car did not diminish her belief. What haunted her was that she could not go back in time to view the accident. This “opportunity” to absolutely ascertain the truth was forever lost. She consequently attempted to give money to the family of the deceased and attempted to arrange for her own arrest.

The “invisibility” of delusional material also applies to many somatic delusions, such as the belief that the insides of one’s body are rotting (typically associated with psychotic depression or schizophrenia). A common delusion among patients with schizophrenia in rural Africa is that a snake has occupied one’s intestines. In these cases, the fact that one cannot directly look inside one’s own body sustains the delusional conviction.

Certain common themes cut across a spectrum ranging from normal to psychotic. Many otherwise normal individuals can be said to have overvalued ideas. These are pet peeves (e.g., the government collects too many taxes) or fixed beliefs (e.g., all men cannot be trusted) that are viewed as meritorious and, therefore, are often shared with or imposed on other people. In contrast, an obsession is a preoccupation that is associated with anxiety, is often viewed as being unhelpful or irrational because day-to-day activities are disrupted, and may thereby be kept entirely private by the patient. In cases of characteristic narcissism, all the ideas arising from an individual are more or less overvalued: “What I do, think, or say should be paid attention to by others.” Grandiosity takes this theme one step further: “What I do, think, or say is better than what others do, think, or say.” Grandiose delusions reflect the extreme case, namely, fixed beliefs that go beyond attributions of individual value or worth by distorting reality, for example, “I am really a rock star, the Pope, Jesus Christ, the next President, the illegitimate son of Queen Elizabeth.” The mirror opposite of this spectrum is also evident. A failure to positively endorse one’s own ideas or self-worth can evolve into hopelessness, suicidality, and a sense of worthlessness.

Another theme that is expressed across the spectrum of normalcy to psychosis involves attributing negative intentions to other persons or groups of people. The normal variant is suspiciousness, that is, a cautious attitude derived from the possibility that certain individuals may be harboring malevolent wishes. In contrast, a phobia reflects fearfulness, not related to the intentions of others but instead to the nonhuman environment (fear of heights, elevators, dogs, and so forth). Paranoia reflects a level of suspiciousness that alters routine activities in nonadaptive ways and is accompanied by a tendency to misinterpret ambiguous events or actions in a fashion that reinforces the attribution of malevolent intentions of others. Intrinsically to the nature of paranoia is the belief in some more or less organized “plot.” For instance, if a person has become paranoid at work it is often accompanied by the belief that one or more individuals share a common goal (e.g., coworkers are trying to get the patient fired), rather than a general, free-floating fearfulness. This leads inexorably to certain types of inferences that are consistent with the paranoid orientation: for instance, that a filing error committed while the patient was working was actually “planted” by a coworker. This belief orientation can reach the level of a paranoid or persecutory delusion, in which reality testing is consistently and obviously distorted to maintain the belief orientation that others are intending harm. The mechanistic basis of paranoia is uncertain. Current experimental evidence suggests that anomalous internal experiences and exaggerated anticipation of threat are important contributing factors (Freeman 2007).

Frequently associated with a paranoid orientation is self-referential thinking, also known as ideas of reference. Individuals with this symptom erroneously attribute high personal relevance or salience to incidental environmental events. They may, for instance, believe that people are paying special attention to them on the street or that strangers seem to be talking about them behind their backs. Numbers on license plates may appear to contain coded messages, and the movement of people or vehicles within the patient’s vicinity may signal special meaning (generally sinister). Other patients report receiving messages from the television or radio, giving them the uncanny sense that the radio or television announcer, song, or commercial somehow has broadcast a message directly to them. Even the specific words or syntax used by others in conversation may seem deliberate and significant, hiding an underlying message. While self-referential thoughts most commonly warn of possible danger, patients with grandiosity may also become self-referential, leading to an expanded sense of self-importance. In any case, self-referential thinking, in turn, can lead to frank paranoid ideation. The individual, in an attempt to make sense of a series of self-referential percepts (and, perhaps, other abnormal experiences such as hallucinations), develops a cognitive scheme that accommodates and explains the “evidence” at hand. Each subsequent instance further confirms the impression that a nefarious plot has been directed toward the patient. This is compounded by the tendency of delusional people toward a hasty reasoning and decisional style in which conclusions are drawn from smaller data sets than are required by nondelusional people (Freeman et al. 2004). Aberrant attribution of salience and subsequent delusion development is at the center of recent hypotheses regarding excess dopamine in psychotic disorders and the role of antipsychotic drugs (Kapur 2003).

Some patients, particularly those who have paranoid tendencies, report abnormal beliefs referred to as delusions of thought control or possession. This involves the belief that other individuals or powers can actually direct the content of one’s own thoughts. These include thought broadcasting (that others can read their minds), thought insertion or deletion (that an external agent has placed alien thoughts or removed the patient’s own thoughts from his or her mind), or that they themselves are capable of mind reading.
Disorders of Thought Content

Alterations in the Experience of One’s Own

Suicidal thoughts are also common and often of major concern. Passive suicidal ideation consists of wishes to be dead, but with no clear intent or plan. Active thoughts about killing or hurting oneself, especially if elaborated into a plan, represent incremental leaps in dangerousness and, often, require hospitalization and careful monitoring. Unfortunately, such ideation can be unpredictable and not always congruent with a depressed mood, as in psychotic states.

A variety of repetitive thoughts, obsessions, ruminations, or delusions may be depressive and self-destructive in content, especially among the mood disorders, schizophrenic disorders, and borderline personality disorders. Hopelessness, feelings of personal worthlessness, and guilt are frequent cognitive schemas that accompany downturns in mood. In their most severe forms, such ideas become delusional reality as convictions that one is dead, dying, doomed, or dangerous. Unrealistic worries about one’s health, or hypochondriasis, can become nihilistic somatic delusions that one’s brain is dust or one’s insides have turned to excrement.

Clinical Vignette 3

When Mr. S entered the hospital, he was 26 years old, single, and had been continuously ill for 9 years, during which time he had been hospitalized 12 times. Despite adequate medication, he could slip into a confused state replete with paralyzing ambivalence and a fragmented delusional paranoid experience in which he felt assaulted by painful tactile hallucinations. During some agitated periods, Mr. S seemed to be experiencing an elemental dread about possessing some powerful, aggressive, evil force capable of destroying his most cherished objects and himself. Once, while pacing, he said to his therapist, “Get out of here! I’m insane! You’re breathing my air!” Later, he told his therapist that mental illness could be passed through the air like germs. While agitated, he often hid his face and later told his therapist it was so he could not see “the flesh peeling off his evil skull, the sight of which could destroy the therapist by driving him insane.

Source: Adapted from McGlashan (1986).

Mr. S’s world was filled with delusions (he was assaulted by the therapist), magical thinking (psychosis is contagious by proximity), grandiosity (he had the power to destroy others), and projected paranoid ruminations (the therapist should fear him and avoid his destructiveness).

Other kinds of thought content disturbances reflect how patients perceive their own mental or perceptual processes. A common example of this sort of disturbance is racing thoughts. Here, thoughts and mental images occur so rapidly that patients themselves cannot keep track of what they are thinking. Often, but not inevitably, racing thoughts are accompanied by speech irregularities such as looseness of association or tangentiality. Some patients can compensate for such thought content disturbances by reducing the rate or amount of speech produced.

A variety of repetitive thoughts, obsessions, ruminations, or delusions may be depressive and self-destructive in content, especially among the mood disorders, schizophrenic disorders, and borderline personality disorders. Hopelessness, feelings of personal worthlessness, and guilt are frequent cognitive schemas that accompany downturns in mood. In their most severe forms, such ideas become delusional reality as convictions that one is dead, dying, doomed, or dangerous. Unrealistic worries about one’s health, or hypochondriasis, can become nihilistic somatic delusions that one’s brain is dust or one’s insides have turned to excrement.

Clinical Vignette 4

A 22-year-old man with two prior episodes of disorganized schizophrenia stopped his neuroleptic medication. Two months later, he lost a bet when his favorite soccer team was beaten in World Cup competition. After the game, while watching a late night television talk show, he became disgusted with what he considered to be a poor performance of the talk show host and decided to kill himself. He took a massive and potentially lethal overdose of a relative’s benzodiazepines and was later taken to the emergency department when he could not be aroused by his family.

Perceptual Disturbances

Sensory impressions of the external world obviously form the basis of much conscious experience. However, much of our conscious experience is generated internally. How do I know that I am thinking of a particular person? I “see” an image of that person in my mind, or inwardly “say” the name. Indeed, we can experience internally generated images involving one or more of all five sensory realms. We can “hear” a piece of music as well as imagine the smell of coffee, a feeling of cotton on the forearm, or hitting a good tennis backhand. All are different kinds of internally generated images that reaccess representational capabilities emerging from the senses. We ordinarily do not label such internally generated images as indicative of psychopathology.

As indicated in our introductory remarks, there is a continuum between ordinary self-generated imagery and pathological hallucination (Hoffman 1986, Strauss 1969). Consider first illusions, namely, external sensory impressions that have been temporarily imbued with a novel interpretation. An example is seeing a cloud pattern that resembles the profile or face of, for instance, a famous figure or one’s father. This experience in itself would not be considered pathological. This same experience becomes a delusional perception if the person maintains the conviction that the face was not an accidental pattern but was in some sense an actual visual recreation of Abraham Lincoln’s face (or the father) that was somehow intended by some force or agency. Here, pathology is intrinsic to inferences that are generated about the percept (delusional attributions) rather than the percept itself.

At the other end of the axis are hallucinations, which in their purest form are perceptions that occur spontaneously (i.e., in the absence of particular sensory triggers).

Illusions and hallucinations are underappreciated aspects of normal experience. Preoccupation with another person (e.g., a lost loved one, a feared authority figure) can result in a fleeting visual illusion among normal individuals, for instance, momentarily seeing the longed-for person in a crowd or at a distance. A person in mourning may see the silhouette of the lost person in a shadow or hear that person’s voice speaking. A common and normal experience is to misperceive indistinct sounds as a spoken word corresponding to one’s own name. Complex visual scenes and sounds can be experienced during daydreams, or at the onset of sleep or waking (Foulkes and Fleisher 1975, Foulkes and Vogel 1965). When especially vivid, such imagery is referred to as hypnagogic hallucination when occurring at sleep onset and hypnopompic hallucination when occurring during drowsiness on waking from sleep. Dreams themselves are clearly hallucinations. Imagery can be quite vivid and ordinarily the dreamer has the sustained conviction of the reality of the dream. It is reasonable to assume that illusion and hallucination are not intrinsically pathological; pathology reflects the duration, prominence, circumstances of occurrence, as well as the relative intrac- tability of beliefs that emerge in response to the experience. For instance, the normal individual quickly realizes that the identity of a misapprehended person was mistaken; the momentary hallucination of a daydream is not retained as an accurate reflection of reality. The psychotic person, on the other hand, may not be able to mentally correct the original misapprehension.

Psychotic states can result in hallucinations related to any one of the five senses. Visions of objects or persons, smells, and tactile sensations can be reported by patients with schizophrenia, mood disorders, similar states caused by medical conditions or induced by drugs, and various forms of epilepsy.

Among schizophrenic patients, however, the most common sensory modality of hallucinations is auditory. Auditory hallucinations can consist of various meaningless sounds (e.g., buzzes, hums, or rumbles), but most commonly spoken words, phrases, or sentences are heard (Hoffman 1986). Hallucinated speech consists of one or many “voices” that ordinarily have distinct acoustic characteristics (such as male versus female, high versus low pitched). For schizophrenic patients, hallucinated voices tend to use words and phrases that are constrained in terms of meaning. For instance, one voice will tend to be highly critical (repetitively using the same words, such as “you are ugly”), whereas another “voice” will repeat reassuring words such as, “I love you.” Hallucinations can express verbal content that is not grammatical, for instance, strings of numbers or jumbled phrases. These hallucinations tend to be repeated and, in time, special meanings are attributed to them by the patient. For instance, one schizophrenic patient repeatedly heard the spoken numbers “three-nine” and came to believe that this was a message from her brother, who was 39 years old. Later, she concluded her brother was actually speaking to her.

Hallucinated “voices” sometimes “sound” similar to the actual voice of someone in the person’s past but more often are experienced as completely foreign. Occasionally, the acoustic qualities of the hallucinated voice are the same as the patient’s own speaking voice. A common denominator is that all are experienced as alien, out of control of the patient, and generated by some outside or nonself agency (often another person, e.g., the CIA, Satan, or God, or increasingly commonly, microelectronic devices). The attribution of alien willfulness is a primary determinant of the level of distress and pathology associated with the hallucination (Hoffman 1986). Vividness of voices (loudness and clarity of the hallucinations) and the degree that the spoken message deviates from the patient’s ordinary thoughts also contribute to overall distress and disruptiveness. Voices that criticize and command the patient to undertake destructive actions such as suicide or assault are especially disruptive and ominous. Some cases of auditory hallucinations consist of multiple speakers carrying on conversations with one another.

Auditory hallucinations are also commonly reported by patients with certain types of dissociative disorders. These hallucinations generally have distinct acoustic characteristics associated with particular internalized “personalities,” with running commentaries or conversational speech that lack the recurrent or idiosyncratic semantic content of “voices” characteristic of schizophrenia. Most often, the hallucinated voices reported by patients with dissociative identity disorder are “heard from within.”

So-called functional hallucinations are intermediate phenomena; they are percept-like and are attributed to an external reality but are merely triggered by an external stimulus. These experiences are not classified as illusions because percepts clearly depart from information derived from an
external stimulus. Functional hallucinations of speech are often reported by psychotic patients, prompted by, for instance, the background noise of running water, fans, or the hum of a refrigerator. For a given patient, the content and vocal characteristics of “voices” triggered by external sound are generally similar or identical to their spontaneous hallucinated “voices.”

**Disorders of Identity and Will**

Some of the most fascinating expressions of psychopathology emerge as disorders of self-experience, variably manifested as problems of will, identity, self-integration, or self-awareness.

Disorders of will (also known as conative functions) are seen most commonly in psychotic states. Loss of willfulness is seen at its most extreme in catatonic waxy flexibility, echolalia, and echopraxia, but in milder forms it can frequently be detected in schizophrenia, depression, obsessive–compulsive disorder, and posttraumatic states. Mania, in contrast, might be characterized as an overabundance of willful intentions.

Patients who experience thought control believe that certain of their thoughts are willed by some agency or person outside their mind or body. Often, different instances of thoughts that are experienced as being controlled have similar content. For instance, a patient might involuntarily and repetitively experience the thought of wanting to kill a spouse. If experienced as his or her own thought, this experience would be classified as an obsession. If the patient believes that the thoughts are placed in his or her head by the devil, these experiences would be identified as thought control of delusional proportion.

Another example of a disorder of will is the delusion of passivity. In this delusion, patients believe that their actions are controlled by some other being or agency.

Among the most striking forms of identity disturbance are distortions of body image, which contain sensory and cognitive elements to varying degrees. With the phantom limb phenomenon after an amputation, for example, the lost arm or leg retains its perceptual reality. In some forms of transsexualism, body distortion is more ideational, that is, the person harbors the conviction that he is really a female trapped in a male body. In this case, reality testing of the actual anatomy is retained, unlike some cases of severe anorexia nervosa in which the patient insists that she is obese despite clear and objective evidence to the contrary. A variety of body image distortions are displayed in body dysmorphic disorder. These are usually cosmetic in nature: imagined defects in appearance become overwhelming obsessions and compel afflicted patients to seek out plastic surgery or other body-altering treatments on repeated occasions. If these ruminations reach delusional intensity and conviction, the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV-TR) (American Psychiatry Association 2000) identifies the syndrome as delusional disorder, somatic type. In this disorder, distortions may become more bizarre (such as a belief of having two heads) and may be accompanied by hallucinations of foul body odor or of insects crawling under the skin (formication).

Dissociation and its related disorders form sets of phenomena that are rich in complexity, often perplexing diagnostically, and occasionally sensational and dramatic in presentation. Dissociation refers to the splitting off of thoughts, feelings, or behaviors from everyday integrated awareness. The dissociative process may involve specific ideas, moods, or deeds, or it may involve complex patterns of behavior, that is, personality states.

It is important to note that dissociation is a normal adaptive mental function. Our everyday tasks of focusing attention and compartmentalizing experience involve dissociation. Normal dissociation is also displayed more explicitly in the phenomenon of hypnosis. The ability to enter different levels of hypnotic trance may be normally distributed in the population. Some people cannot experience hypnosis; other people enter deep trances easily (somnambulists); most people range somewhere in between. The trance state is a mixture of intense absorption with one idea or activity, dissociation from other experiences and sensations, and heightened suggestibility to instruction and demand characteristics of the social situation (Orne 1959, Spiegel and Spiegel 1987). In dissociated hypnotic trance states, anesthesia can occur by suggestion (McGlashan et al. 1969), and other alterations in consciousness can be induced that mimic many of the DSM-IV-TR dissociative disorders, for example, positive and negative (pseudo)hallucinations, voluntary muscle (conversion) paralysis, posthypnotic amnesias, and posthypnotic suggestion.

The phenomenology of posttraumatic disorders may represent another form of normal dissociation insofar as dissociation represents a normal response to major stress (“I am not here” or “This is not happening to me”) that fosters adaptation under extreme conditions. The subsequent interaction between reexperiencing memories (often with hallucinatory vividness) and symptoms of distancing or numbing may also represent dissociation at work in modulating the psychological processing and integration of trauma. When the dissociative process is prolonged and perseverative, however, it becomes pathological, and disorder supersedes adaptation.

A relatively common dissociative disorder of self-experience is depersonalization. Patients with this syndrome report that they feel detached or estranged from themselves. Other associated symptoms include feeling like an automaton, a sense that one is actually outside one’s own body, or feeling that parts of one’s body are detached from each other (Jaspers 1911). A related symptom is derealization, which consists of the experience that one’s self is somehow removed from the world, or that the immediate sensations of the environment are unreal or somehow inaccessible. This
 constellation of experience can be seen normally at times of exhaustion or bereavement and is associated with many psychiatric disorders, including schizophrenia, panic disorder, substance-induced states, and dissociative disorders, or it may occur as a separate disorder. The most intense and concrete form of derealization may be hysterical conversion, in which sensory anesthesia or motor paralysis ensues based on a dissociated idea.

Other dissociative disorders less frequently encountered involve amnesias, that is, whole time periods lost to memory, usually associated with some negative experience. Rarely, patients may develop a fugue state, that is, amnesia of their entire past in which they adopt a new identity in life. Most publicized but perhaps rarest of all is dissociative identity disorder, or the appearance of more than one distinct identity or personality states in the same person. Several personality states are the rule, usually manifested one at a time and usually dissociated from each other with varying levels of awareness. These identities or personality states have their own characteristic profiles. When a person with dissociative identity disorder is in a particular personality, he or she may talk and dress differently and even assume a different name.

Some psychotic syndromes appear related to dissociation and depersonalization, at least on a phenomenological level. The mididentification syndromes represent such entities. Examples include Capgras’ syndrome, in which patients report that other people are no longer real or are doubles, and Fregoli’s syndrome, in which patients believe that a seeming multiplicity of persons are actually one individual reappearing in various disguises. These beliefs can extend to family members and friends, that is, individuals who are known intimately by the patient. This experience is captured in the well-known movie Invasion of the Body Snatchers.

Another rare disorder of identity is called pseudologia phantasica. In this disorder, patients are compelled to enact certain belief orientations or assume certain roles even though they know that it is “all an act.” An example of this disorder is given in the following vignette.

Clinical Vignette 5

A 28-year-old woman, during a period of 2 years, was compelled to portray herself as the daughter of a famous actress. This included changing her name, writing fictitious letters from the actress to herself, and arranging for herself to receive fake telephone calls and telegrams. All the while she was very afraid that she would be discovered as a fraud.

Probably related to pseudologia phantasica is Munchausen’s syndrome. The syndrome is named after Baron von Munchhausen, a German soldier and traveler of the eighteenth century who was legendary for his exaggerated tales of accomplishment. The medical use of the term is restricted to patients who feign medical disorders. These individuals, for instance, may swallow blood and induce vomiting to mimic a bleeding ulcer or present in an emergency department with all the signs and symptoms of a perforated appendix. These individuals are often successful in obtaining extensive medical treatment, including multiple major surgical interventions. Patients who feign the symptoms of mental disorders to become patients (but not for external incentives, such as obtaining financial benefits) are diagnosed as having a factitious disorder.

Finally, dissociation is common among psychotic disorders as an obvious curtailment or incongruity of feeling with respect to expressed ideas. The former is referred to as blunted affect, the latter as inappropriate affect. Both are common in schizophrenia.

Clinical Vignette 6

Mr. B’s onset of schizophrenia came at age 14. By age 21, he had experienced three hospitalizations covering a total of 2 years. He seldom experienced differentiated feelings and reported bafflement with people who did. In one therapy session, he said, “I have an assumption that I’m alive,” and he noted that he couldn’t “hold on to” feelings about people from the past like his mother and father. He said “You see, I would die if I was feeling . . . I don’t have natural reality like others because I’m not living. I’m always in a place of ever death . . . you have a language that I don’t understand though I know you want me to learn it. You want me to want.”

Source: Adapted from McGlashan (1986).

Agnosias are massive deficits in self-experience usually related to brain damage. They consist of failures to recognize major changes in one’s self and functioning. For example, in autotopagnosia, there is denial of hemiparesis and/or blindness (usually left sided) secondary to right parietal lesions, most frequently resulting from stroke. Sometimes, the raw sensory data are intact but the patient is unable to interpret their significance and meaning. In visual agnosia, objects and people are seen but not recognized. In astereognosis, objects cannot be recognized by touch. In prosopagnosia, faces cannot be identified.

The most common and striking agnostic deficit is anosognosia, in which the patient steadfastly refuses to acknowledge that she or he has any illness despite overwhelming evidence to the contrary. Sometimes disability is acknowledged cognitively but not affectively or conatively. The patient persistently ignores the problem and behaves as though it is not there even when the presence of the disorder is acknowledged on direct questioning. This anosodiaphoria or indifference to disability is seen in a milder, functional form as la belle indifférence, or calmness in the face of disability associated with conversion hysteria.

Unawareness of illness can take many other forms and is commonly part of psychiatric disorders, especially the psychoses (Prigatano and Schacter 1991). Some form and degree of illness denial or lack of awareness can be seen in most cases of schizophrenia, although the effect of this deficit on judgment and treatment compliance is hard to predict.

Insight is a complex construct with many levels, and loss of insight can become manifest at each level. Complete insight into schizophrenic illness, for example, involves understanding the nature of schizophrenia as a psychotic mental disorder and the lifelong treatment implications of having that diagnosis. At a less than complete level, patients acknowledge that something is wrong and that they need help. Insight is further truncated in patients who deny illness but recognize that others think differently and want the
patients to accept treatment for everyone’s peace of mind. Many patients deny vehemently that illness is present when asked, but nonetheless behave in total compliance with the treatment expectations presented to them. Finally, there are those, unfortunately all too common, who are unaware of their illness and noncompliant with treatment. Here, lack of insight has a profound and, often, destructive effect on judgment.

**Conclusion**

Our psychiatric nomenclature reflects the fact that disorders of speech, thought, perception, and self-experience fall along a continuum ranging between normal and extremely disturbed. We have tended to discuss each manifestation singly. However, it should again be stressed that symptoms in one realm commonly cross over and influence or induce symptoms in other realms. For instance, a patient with a delusion or severe obsession might be pulled conversationally off track during a clinical interview, producing tangentiality or circumstantiality. A pattern of illusory misperceptions, for instance, momentarily seeing the face of a deceased relative on multiple occasions, could induce the delusion that the relative has come back to life. Moreover, this process could work in reverse; delusional preoccupations often induce misperceptions that support the delusion.

No particular sign or symptom is pathognomonic of a specific psychiatric disorder. Clinical assessment is, instead, designed to generate a gestalt consisting of multiple signs and symptoms that tend to cluster together, which identifies particular psychiatric disorders. These disorders are discussed individually in later chapters.

Behavioral, Neurological, and Cognitive Components of Emotion

Emotion is a subjectively experienced feeling that is related to affect and mood. The experience of emotion occurs through a set of expressive behaviors, the function of the nervous system, and cognitive perception or appraisal. Emotion has behavioral, somatic, and psychic components.

Emotions are not a single response but a collection of responses and are always varied and complex. Emotions are induced by objects or situations that come from interactions with the environment, or from within as representations of internal milieu states. Both internal and external perceptual recall can occur outside of consciousness and induce an emotional response. Emotions are linked to certain inducers and result in consistent responses suggesting their early specification in the nervous system (Damasio 2000).

Charles Darwin’s (1872) work on facial expression pioneered the role of expressive behaviors in emotion. Darwin stated that the complex behavioral actions associated with emotions occur to relieve or gratify sensations or desires and that the same movements are repeatedly performed through force of habit. Furthermore, when the opposite state of mind is induced, there is an involuntary tendency to perform movements of the opposite nature. He believed that the behavioral expression of emotion is driven by the nervous system independent of will and, to a large part, independent of habit.

The basic patterns of emotional expression are present at birth and vary little with age and across cultures. By 3 months of age, infant and adult facial expressions of certain emotions are similar (Emde et al. 1978, Emde 1980). The facial expressions and emotions of infants differ little cross-culturally (Bowlby 1973), although more recently this has been brought into question (Camras et al. 2003). It is this nonverbal expression of emotion that the infant uses to communicate with the parent and that the parent uses to determine the needs of the infant. Although emotional expression is considered innate, it can be modified through learning and maturation (Barlow 1988).

Ten basic, fundamentally different expressions of emotion have been proposed by Izard (1977) (Table 36–1).

These different emotions can be combined with one another to produce distinct behavioral reactions within and between individuals (Barlow 1988). The basic emotions are differentiated not only by behavioral expression but also at the psychophysiological and neurobiological levels. The expressive behavioral tradition for the study of emotion assumes that it is the expressive behavior that results in the experience of affect through autonomic or central nervous system activation and that facial expression is the primary component of emotion (Barlow 1988).

A related theory, known as the James–Lange theory (James 1890), proposes that body changes that differ between the basic emotions are a response to a predisposing event, but the sensation of these body changes, and not the event, leads to the expression of the emotion. The view that emotional expression is hardwired is incomplete because the behavioral, experiential, and somatic or physiological components of emotion are often not correlated (Barlow 1988).

The role of the nervous system in the study of emotion was initiated by Walter Cannon (1929) in experiments in which he surgically removed areas of animal brains. These studies of emotion as primarily a function of the brain suggested that the areas of the brain associated with emotion are phylogenetically more ancient and primitive. Pathological emotions involve the deep brain structures more than the cerebral cortex. Emotional activation may occur without the activation of higher cognitive processes and perhaps through connections with the retina (Moore 1973, Zajonc 1984). The

The prefrontal cortex is involved with regulation of emotions, as demonstrated by the famous case of Phineas Gage (Harlow 1868), who became impulsive, restless, and disrespectful after damage to the anterior part of his frontal lobe by a railroad iron bar exiting through his forehead from an explosion. Activation in the orbitofrontal and inferior frontal cortex is associated with suppressing and reappraising negative emotional stimuli. Increased prefrontal cortex activity is believed to decrease amygdala activity, a key brain region related to extinction—the weakening of a response to a stimulus, during regulation of emotions (Quirk and Beer 2006). The medial prefrontal cortex integrates cognitive affective information and regulates the hypothalamic pituitary adrenal axis in response to emotional stress (Radley et al. 2006). The regulation of fear after extinction has been found to involve the hippocampal–prefrontal cortex (Kalisch et al. 2006). The role of the prefrontal cortex in extinction has broad clinical implications, as some emotional disorder are characterized by a resistance to extinction of learned emotional anxiogenic stimuli and an avoidance of situations with the potential to induce extinction (Sotres-Bayon et al. 2006) (see Figure 36–1). Table 36–2 provides a summary of damage to specific areas of the brain associated with emotional regulatory deficits.

Neurotransmitters and their presynaptic and postsynaptic receptors seem to mediate emotion within the central nervous system. The possible role of norepinephrine in depression has been suggested by the catecholamine deficiency hypothesis. Many antidepressant drugs increase synaptic concentrations of norepinephrine, whereas reserpine, a catecholamine-depleting drug, causes depressive symptoms (Bunney and Davis 1965, Schildkrout 1965). The indolamine hypothesis postulates that depression results from deficits in serotonin. The gamma-aminobutyric acid, noradrenergic, glutamatergic, and serotoninergic systems have all been shown to mediate forms of anxiety.

A third approach to the study of emotion has been based on the cognitive characterization of emotion. Two competing cognitive explanations have been posited: the appraisal theory and Lang’s bioinformational approach. The appraisal theory (Schacter and Singer 1962) suggests that emotion is a result of the individual’s appraising the context of a situation, attributing a causal relationship after the perception of a generalized, undifferentiated arousal state. There is little evidence to support this theory in its entirety, because emotion can occur in the absence of arousal (Barlow 1988). Emotion has also been viewed by alternative appraisal theories as an adaptive behavior, which follows changes in the environment that are evaluated in terms of their potential impact on the individual (Lazarus 1968, Lazarus et al. 1970). The appraisal model suggests that an evaluation or appraisal of the environment is connected to the initial stimulus preceding and modifying the emotion. For subsequent stimuli, a reappraisal of the earlier situation may ensue. The emotional response is case-based on associative reasoning and provides a preparedness function (Ortony et al. 1988). Appraisal theory has difficulty explaining irrational emotions (Barlow 1988) unless information is appraised and processed by use of an unconscious process (MacLeod et al. 1986). A modification of this theory is the modal model of emotion that has three elements: one, emotions arise when an individual
attends to a situation and sees it relevant to their goals; two, emotions result in changes in subjective experience, behavior, and central and peripheral physiology; and third, a response that may be modulated. Emotions are regulated by five families of processes: situation selection, situation modification, attentional deployment, cognitive change, and response modification (Gross and Thompson 2007) (see Figure 36–2).

An alternative cognitive explanation of emotion is the bioinformational approach (Lang 1985). Emotion involves processing and accessing information stored in memory. Information on both the stimulus and the response is stored in memory. This information is then interpreted on the basis of the significance of the event, allowing expression of the appropriate emotion in intensity consistent with the stimulus.

Research into emotional states based on factor-analytical approaches has resulted in various models to characterize the range of emotional expression. Factor analysis of dimensions of affect and personality has given rise to dimensional models, which are considered theoretical models to describe not only emotion but also personality. Dimensional models usually attempt to describe emotions in only two or three bidirectional dimensions, such as Eysenck (1967) two-factor model. One axis is called introversion–extroversion, and the other neuroticism–stability.
Affect and Mood

Disturbances in Affect

Eysenck’s biological theory, emotions are associated with an individual’s level of arousal that is set either too high or too low by the reticular-activating system. Extroverts seek out greater stimulation because of low levels of arousal, whereas introverts, who have high levels of arousal, need less stimulation. Neuroticism is theorized to involve the autonomic nervous system; neurotic individuals have increased reactivity in the autonomic nervous system. Emotion results from the interaction of these two axes and the limbic system.

An alternative approach is the circumplex model, in which emotions are placed in a circular order reflecting their relationship to other emotions. The opposite emotion is on the other side of the circle. Tellegen (1985) created a circumplex model that is divided into eight sections: strong engagement, high negative affect, unpleasantness, low positive affect, disengagement, low negative affect, pleasantness, and high positive affect. This model can be used to capture the distinction between an anxious, depressed, or manic mood and affect, as well as to demonstrate that these moods are a continuum. An anxious mood is considered to be a high negative affect, with descriptors such as distressed, fearful, hostile, jittery, nervous, and scornful. A depressed mood in the circumplex model would be a low positive affect, including descriptors such as being drowsy, dull, sleepy, and sluggish. A manic affect would be captured by terms in the high positive affect dimension: active, elated, enthusiastic, excited, peppy, and strong.

The strength of an emotion may be amplified, attenuated, or maintained, which is referred to as emotional regulation (Thompson 1994) or affective style (Davidson 1998). Through this process the individual can be distracted from aversive stimuli and generate imagery to replace unwanted emotions (Derryberry and Reed 1996), making it difficult to interpret where emotions end and regulation begins.

Assessment of Mood and Affect in the Clinical Interview

Two terms are often used to refer to an individual’s emotion: affect and mood (Table 36–3). In the absence of a psycho-pathological process, affect fluctuates with time and context and ranges from sadness to anger to elation, depending on the emotional state. Affect can be expressed through autonomic responses, body movements, and alterations in speech to concrete or abstract stimuli. Observing a violent act exemplifies a concrete stimulus that could lead to the expression of fear; hearing the abstract term love could result in the expression of an elated affect. Speech changes that reflect affect include tone of voice, vocalization, and word selection. Visible autonomic changes that may reflect changes in affect include sweating, trembling, blushing, and becoming flush. Changes in posture, alterations in facial expression, reactive responses, and grooming movements are body changes seen in expression of affect. Reactive movements include movements of the body and face made in response to a novel stimulus, such as in a startle response, when an individual jumps or turns and looks at the stimulus. Changes in facial movements of the mouth, nose, and eyes are found with different affective states. Manipulation of one’s appearance is common in states of discomfort; individuals may fix their hair, clean their nails, scratch, or straighten their clothes.

Affect has three functions: self-perception, communication, and motivation (Othmer and Othmer 1994). Self-perception is the emotional value judgment or the affective evaluation where emotions end and regulation begins. Social and cultural norms determine whether an affect is appropriate or disturbed for a given situation. Disturbances in affect (Table 36–4) may be quantitative or qualitative and include blunted, flat, inappropriate, labile, and restricted or constricted affect (American Psychiatric Association 2000, p. 819). An appropriate affect, the normal condition, is exemplified by people who are able to express the full range of emotions in a manner consistent with their thoughts and speech.

Evaluation of affect consists of monitoring gestures, body movements, and facial expressions. Because adults are frequently capable of controlling facial expression in attempts to intentionally or unintentionally suppress their affect, other behavioral gestures may give clues to the underlying affect. The quality, duration or mobility,
The range of the affect is characterized by the variety of emotional expressions noted in a session. Normal individuals express different feelings at different times. Patients who appropriately express many different emotions have a full or broad range of affect. A restricted range of affect is seen in individuals who have a limited emotional expression, whereas a fixed or immobile affect is found in those who display only one type of emotion. The intensity of affect (the strength of the emotional expression) normally varies according to the situation. Those with limited emotional expression may have a blunted or a flattened affect. The mobility of affect is the ease and speed with which one moves from one type of emotion to another. Changes in the type and intensity of emotional expression normally occur gradually. Reduced mobility in affect is also referred to as constricted affect. When the affect is extremely constricted to one emotion, it is called a fixed or immobile affect. When no affect is displayed, it is reported to be flat. Pathologically increased mobility of affect is referred to as labile. The reactivity is the extent to which the affect changes in response to an environmental stimulus. When the patient does not respond to the examiner’s provocation, such as joking, the affect is nonreactive (Manschreck and Keller 1989, Trzepacz and Baker 1993) (Table 36–5). (Table 36–7). A particular mood is not necessarily abnormal or pathological but must be evaluated in the context of the patient’s entire history and psychiatric mental status examination.

Mood and affect are related but differ in their pattern of stability over time. Affect fluctuates, whereas mood is a more pervasive and sustained emotional state (American Psychiatric Association 2000, p. 825). Unlike affect, which is observed, mood is not always readily discernible or observed but may need to be reported. An alexithymic person is unable to verbalize or has difficulty describing or being aware of emotions or moods. Mood colors an individual’s perception of the environment. Mood can be characterized as dysphoric, elevated, expansive, irritable, or euthymic (Table 36–6). Mood is described by its quality, stability, reactivity, intensity, duration, and congruence with thought content all of the Axis II disorders contain at least one specific emotion that is affect related. Table 36–8 lists the specific criteria that affect related for each of the personality disorders (Clark 2000). In borderline personality disorder emotional dysregulation, the inability to change or regulate emotional cues, experiences, actions, verbal responses, and nonverbal expression has been proposed to explain their greater emotional sensitivity, greater emotional reactivity, and slower return to baseline arousal (Figure 36–3) (Linehan 1993).

### Emotional Expression of Anxiety

#### Spectrum of Anxiety

Anxiety is an emotion characterized by apprehension and anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension (American Psychiatric Association 2000, p. 820). The perceived danger may be either an internal or an external fear. The physiological manifestations of anxiety (Table 36–9) may present as symptoms of activation of the autonomic nervous system. Anxiety is a normal reaction to a situation where immediate danger exists and may result in physical harm. Anxiety is also a normal response to situations that pose a threat to self-esteem or psychological well-being. Pathological anxiety occurs in situations where there is no real physical or psychological danger or when the emotional
reaction is disproportionate in intensity to the actual danger (Spielberger and Rickman 1990).

Etiology of Anxiety
Traditionally, the emotion of anxiety has been dichotomized into fear and neurotic anxiety. Fear, or objective anxiety, as conceptualized by Freud (1936, 1959), consisted of three components: a real external danger, an accurate perception of the danger as potentially harmful, and an emotional response of anxiety, which varied in intensity proportional to the magnitude of the objective danger. Neurotic anxiety, as Freud described it, was also a psychobiological process; however, the danger was from within, in the form of forbidden instinctual drives that were punished in childhood, repressed, and subsequently about to escape from the individual’s control (Spielberger 1966). Fear and anxiety may be present in varying proportions in a given situation. Elucidating the cause of the affect is more important clinically than determining whether the emotion is fear or anxiety (Uhde and Nemiah 1989).

More recent theories of the emotion of anxiety can be divided into stimulus- and response-oriented theories. The former construct suggests that stimulus events serve to initiate the emotional response. It is the nature of the event (the thoughts, feelings, and situation associated with the event) that precipitates the response. An example of a stimulus-oriented theory is Goldstein (1940) catastrophic reaction. A situation that represents a threat to the individual’s existence, physical or psychological, is necessary for impairment of objective behavior resulting in the subjective experience of anxiety.

Fear may result in anxiety disorder when it becomes greater than warranted or occurs in inappropriate situations. LeDoux (2000) has proposed that anxiety may develop as a conditioned response to fear following exposure to the unconditioned stimuli, not dissimilar to conditioned response proposed by Pavlov (1927). Subsequently, exposure to a conditioned stimulus mediated by the amygdala leads to activation of a defensive behavior, autonomic arousal, hypoalgesia, somatic reflex potentiation, and pituitary–adrenal axis activation.

The response-oriented approach focuses on the resultant affect. The response-oriented theorists hold that the anxiety response is the same regardless of the stimulus. Anxiety is an innate emotion resulting from a neurophysiological response that can be modified through learning. Pathological anxiety differs from normal anxiety by the increased intensity, frequency, and duration of the neurophysiological response.

The trait–state dichotomy (Cattell and Scheier 1961) of anxiety is an outgrowth of the response-oriented theorists. Trait is viewed as a personality feature, whereby the individual consistently behaves anxiously despite the situation. State refers to momentary feelings of anxiety. Despite some detractors to this theoretical distinction (Allen and Potkay 1981), the validity of this dichotomy has been shown in research demonstrating trait anxiety to remain stable over time and to be impervious to stress, despite circumstances (Spielberger and Rickman 1990). The stimuli that elicit anxiety, according to trait–state anxiety theory (Figure 36–4), may be either intrapsychic or from environmental sources. Anxiety from situations that threaten personal adequacy is found more often in individuals with high trait anxiety.

Other cognitive theories of anxiety are outgrowths of the response-oriented view. Beck and colleagues (1974) believed that anxiety results from a misperception of danger or an unrealistic heightened expectation of harm. The degree of the anxiety is directly proportional to the anticipated severity of the adversity and the degree to which the individual cognitively distorts these fears (Table 36–10). The phenomenology and maintenance of anxiety has been proposed to be a result of counterproductive efforts to regulate emotions. That core features of anxiety, such as worry and behavioral avoidance, are maladaptive attempts to regulate uncomfortable or unwanted emotions (Campbell-Sills and Barlow 2007).
Kagan and colleagues have suggested that behavioral inhibition in childhood may be an antecedent of anxiety disorders in adulthood. Children with an inhibited temperament tend to be timid with people, objects, and situations that are novel or unfamiliar. They have found that children of parents with panic disorder with agoraphobia, including those with comorbid major depressive disorder, are at increased risk of behavioral inhibition; children identified as having behavioral inhibition have high rates of childhood-onset anxiety disorders; behavioral inhibition is associated with familial risk for anxiety disorders; children with behavioral inhibition and anxiety disorders have greater familial anxiety disorders; and children who remain inhibited over time are at highest risk of anxiety disorders (Rosenbaum et al. 1993).

Clinical Presentation of Anxiety
Anxiety is an emotion that may be present in many psychiatric disorders as well as other medical conditions (Table 36–11). Anxiety may be a prominent feature in numerous neurological disorders, hypoxic states, and endocrine disorders. Uremia, posthepatitis syndrome, infectious mononucleosis, porphyria, febrile illnesses and chronic infections, systemic malignancies, carcinoid syndrome, and hypoglycemia have been implicated in producing states of anxiety. Inflammatory diseases and some vitamin deficiencies have also been implicated. A number of toxic agents have been shown to result in anxiety (Cummings 1985).

Anxiety is a common symptom in psychosis, mood disorders, organic disorders, delirium and dementia, and somatoform disorders. Anxiety is the prevailing mood state in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revised (DSM-IV-TR) anxiety disorders: panic disorder without agoraphobia, panic disorder with agoraphobia, agoraphobia without history of panic disorder, specific phobia, social phobia, obsessive–compulsive disorder, posttraumatic stress disorder, acute stress disorder, generalized anxiety disorder, anxiety disorder due to a general medical condition, substance-induced anxiety disorder, and anxiety disorder not otherwise specified (NOS). Anxiety is also the prominent feature in adjustment disorders with anxiety.

The clinical presentation of anxiety symptoms varies with the specific disorder. Panic attacks may be present in nearly all the specific anxiety disorders. A panic attack is described as a sudden, discrete period of intense apprehension, fearfulness, or terror associated with physical symptoms including shortness of breath, palpitations, and chest discomfort. During a panic attack, the individual frequently

has feelings of impending doom, a fear of losing control, a sense of imminent danger, and an urge to escape. Panic attacks are divided into three characteristic types by the onset of the attack in relation to the presence or absence of a situational stimulus (Table 36–12). Unexpected panic attacks occur spontaneously, unassociated with a situational trigger. Situationally bound panic attacks occur immediately on exposure to or in anticipation of a situational cue. Situationally predisposed panic attacks are more likely to occur on exposure to a specific stimulus but do not necessarily occur immediately. Unexpected panic attacks are necessary for a diagnosis of one of the panic disorders. Situationally bound panic attacks are characteristic of social and specific phobias. The situationally predisposed panic attack occurs in panic disorder, specific phobias, or social phobias.

The characteristic presentation of anxiety in phobic disorders is a persistent, irrational fear of a specific object, activity, or situation that results in a desire to avoid it. When exposed to the stimulus, the phobic individual experiences intense, autonomic symptoms associated with fear. The response is frequently difficult to distinguish from the anxiety of panic disorder, which is characteristically spontaneous and not situationally provoked. Anxiety symptoms associated with increased arousal, reexperience of a traumatic event, and avoidance of stimuli reminiscent of the trauma are characteristic of both acute and posttraumatic stress disorders. Obsessions, persistent ideas, thoughts, impulses, or images that are intrusive and inappropriate result in the distress and anxiety characteristic of obsessive-compulsive

Demoralization is a condition of low self-esteem, helplessness, hopelessness, sadness, and anxiety (Dohrenwend et al. 1980). Demoralization is experienced in a variety of situations including severe physical illness, chronic illness, and conditions of marginalization as well as psychiatric disorders. The degree to which an individual is demoralized can be considered her or his psychological temperature and may provide a conceptual continuity of depressive symptoms from normalcy to clinical disorder.

Sadness appropriate to a real loss is part of mourning or grief. The depressed affect accompanying grief differs from other depressed states by a sense of relief felt with the expression of grief (Jacobson 1974). A depressed mood accompanied by poor appetite, weight loss, and insomnia commonly occurs during bereavement. If bereavement is also associated with morbid preoccupation with worthlessness, guilt about things other than actions taken or not taken by the survivor at the time of death, thoughts of death other than the survivor feeling that he or she would be better off dead or should have died with the deceased person, prolonged and marked functional impairment, marked psychomotor retardation, or hallucinatory experiences other than thinking that he or she hears the voice of or transiently sees the image of the deceased person, this suggests that the bereavement is beyond the expected norm and that a major depressive episode is present. The duration and expression of normal bereavement vary considerably among different cultural groups.

Etiology of Depression

Theories of the origins of pathological depressed mood states can be found in the Hippocratic writings of the fourth and fifth centuries. These early writings defined melancholia to be a prolonged state of depression, with associated aversion to food, despondency, sleeplessness, irritability, and restlessness. Of the four humors, blood, yellow bile, black bile, and phlegm, an excess of black bile was thought by the ancient Greeks to play a distinct role in the development of melancholia. The introduction of the term depression as a substitute for melancholia in the mid-1800s began to signify a psychological and not merely physiological understanding of depressive mood states. Modern conceptualizations of the etiological origins of the emotion of depression encompass a broad theoretical spectrum, including early environmental, personality, psychodynamic, cognitive, life events and social stress, and neurobiological theories.

Early environmental theories considered parental loss, parental separation, and parental style to be risk factors for depression. There is little evidence in experimental controlled studies to support a relationship between parental loss by

### Clinical Vignette 1

A 45-year-old man was seen in the emergency department. He was dressed in a hospital gown and was observed to be hyperventilating, clutching his chest. He kept yelling out, “I’m dying. I’m having a heart attack, I can’t breathe.” His electrocardiogram, laboratory, and physical examination findings were all normal except for an elevated blood pressure. The patient was diaphoretic and restless and also complained of thirst. This was his third admission to the coronary care unit on the other occasion, with no evidence of a myocardial infarction. The patient was admitted to the coronary care unit this week to the emergency department. The patient was admitted to the coronary care unit on the other two occasions, with no evidence of a myocardial infarction. He appeared to be irritable and anxious. His speech was loud. When interviewed, he acknowledged feeling “wound up, nervous, and anxious.” His affect during the interview was labile, full range, reactive, and mainly appropriate but exaggerated. He stated that he did not know what caused these attacks and that they came “out of the blue.” Between episodes, he felt somewhat “nervous” but mainly “all right.”

### Emotional Expression of Depression

**Spectrum of Depression**

Depression refers not only to an emotional state that is characterized by brief or mild periods of sadness or being “down” but also to a clinical condition characterized by depressed mood. A sense of helplessness or loss of self-esteem is often present in a depressed mood. Sadness, dejection, self-reproach, helplessness, despair, feelings of rejection, pessimism, and boredom may be terms used to describe the dysphoric, painful, or unpleasant feelings associated with depression (Hamilton 1982). Depressed mood states are present in simple unhappiness, grief or bereavement, demoralization, and mood disorders.
death in childhood and depression in adulthood (Crook and Eliot 1980, Tennant et al. 1980, Canetti et al. 2000). The role of parental separation appears to be more complex; separations involving family discord, such as divorce, may have a long-term impact (Canetti et al. 2000); and studies that have suggested a role for parental death in major depression in adulthood have found a more robust role for parental separation (Agid et al. 1999). However, methodological issues in this area of research continue to create speculation as to the validity of such findings (Tennant 1988), in particular, the lack of adequate accounting of the effects of genetic and environmental factors preceding the loss. Parental styles from rejecting and indifferent to overprotective and controlling have been posited to predispose to adult depression; however, evidence of a causal relationship is yet to be demonstrated. Adult attachment, insecure attachment, has been shown to lead to depressive symptoms in adulthood through its impact on self-worth contingencies and self-esteem (Roberts et al. 1996).

There are four major models for the role of personality in depression: vulnerability model, complication model, spectrum model, and pathoplasty model. The vulnerability or predispositional model considers that certain antecedent personality characteristics render an individual vulnerable to the development of depression. An example of this model is Cloninger (1987) theory that neurobiological processes interact with heritable personality traits. He stated that there are three underlying dimensions of personality defined by their stimulus–response characteristics that are genetically and neuroanatomically based: novelty seeking, harm avoidance, and reward dependence (Figure 36–5). Susceptibility to reactive dysphoria is primarily determined by high reward dependence and reduced by high harm avoidance and high novelty seeking (Cloninger 1986).

The complication model is the reverse of the predispositional model. According to this model, clinical depression leads an individual to change the way she or he interacts with others or perceives herself or himself. The spectrum model proposes a continuum between temperament and mood disorders. Pessimism, moodiness, passivity, negativity, and low energy may be personality characteristics that represent the same genetic endowment in normal or milder depressive states as in pathological syndromes. Akiskal and Akiskal (1992) have suggested that cyclothymic, depressive, and hyperthymic temperaments represent the subclinical foundations from which affective episodes arise (Table 36–13). The mechanism postulated by the fourth model, the pathoplasty model, that symptomatic expression and course of depression are influenced by personality characteristics has not been demonstrated in studies measuring personality attributes before the development of a depressive episode (Angst and Clayton 1986, Hirschfeld et al. 1989, Lewinsohn et al. 1988, Nystrom and Lindegard 1975).

The psychodynamic understanding of depression has evolved with the development of psychoanalytic theory. It holds that depression is the result of disturbance of self-esteem in the context of failed interpersonal relationships. These childhood relationships are internalized and reactivated with the onset of depression. These object relationships are also externalized into current relationships. There is a close relationship between the individual’s intimate interpersonal interactions and the maintenance of self-esteem in depression (Gabbard 1994).

The best-known cognitive theory of depression is put forward by Beck (1967). Beck claimed that the principal etiological agent in the development of depression is inaccurate cognitions. It is these distorted thoughts that result in the self-defeating and pathological emotional responses experienced by individuals with depression. The study of dogs

![Figure 36-5](https://example.com/figure36-5.png)
exposed to inescapable shock has led to the learned helplessness model of depression. Seligman (1974) found that animals developed a passive acceptance of the condition in subsequent situations when escape was possible. In the learned helplessness condition, the animal was unable to initiate adaptive responses. This model was thought to apply to the pathological expression of the emotion of depression. Based on epidemiological studies of twin pairs, men and women have been shown to have more similarities than differences. Three pathways to depression in men and women were suggested, characterized by internalizing symptoms (genetic risk factors, neuroticism, low self-esteem, early-onset anxiety, and past history of major depression), externalizing symptoms (males: genetic risk factors, conduct disorder, and substance misuse; females: conduct disorder, substance misuse, and past history of major depression), and adversity and interpersonal difficulty (low parental warmth, childhood sexual abuse and parental loss, low education, lifetime trauma, low social support, history of divorce, past history of major depression, marital problems, and stressful life events) (Kendler et al. 2002, Kendler et al. 2006). In both sexes, genetic factors were important in the pathways to neuroticism, substance misuse, lifetime traumas, past history of major depression, and risk of major depression in the past year. The genetic factors for both genders are mediated partially by personality, increased exposure to traumatic events, and substance misuse. Childhood parental loss and low self-esteem had a more potent effect on men than on women.

Physiological explanatory models have become the primary focus in understanding the origins of depression. Subcortical and limbic brain structures and their ascending projections are believed to mediate depression. Biochemical theories have implicated disturbances in norepinephrine, serotonin, and dopamine in the pathogenesis of depression. Dysfunction of the hypothalamic–pituitary–adrenal (HPA) axis has been consistently observed in patients with major depression, presenting as elevation of basal cortisol dexamethasone-mediated negative feedback resistance, increased cerebrospinal fluid levels of corticotropin-releasing factor (CRF), and a blunted adrenocorticotropic hormone (ACTH) response to challenge with exogenous CRF (Plotsky et al. 1998). None of these etiological mechanisms, biological or psychological, is sufficient to explain the development of the pathological expression of the emotion of depression.

### Clinical Presentation of Depression

A dominating depressed mood state may be seen in numerous general medical disorders (Table 36–14) as well as in psychiatric disorders. A number of neurological conditions may result in a depressed mood including Parkinson’s disease. In cerebrovascular disease, depression is more common with frontal lobe lesions than with posterior hemisphere lesions, and it is more common with left- rather than right-sided infarcts (Robinson et al. 1984). Cardiopulmonary disease, renal disease and uremia, systemic neoplasms, porphyria, Kluneafelters’ syndrome, postoperative states, and acquired immunodeficiency syndrome may all present with disorders of emotion, often depression. Less common but documented are deficiencies of vitamin B12, folate, and vitamin C resulting in depression. Endocrine disorders, inflammatory diseases, bacterial and viral infections, and a broad spectrum of pharmaceutical agents may result in development of depressed mood states. Of the hypertensive drugs,

etiological factors in the development of depression. Such studies have demonstrated a cause-and-effect role for these social risk factors; however, these models can explain only a small proportion of the variance for the occurrence of depression.

Theories of social stress have examined stressful life events (Brown and Harris 1978) and social support (Aneshensel and Stone 1982, Williams et al. 1981) as
The mood disturbance characterized by a major depressive episode involves both cognitive and vegetative symptoms. These vegetative symptoms, referred to as such because they are unconscious and involuntary, include changes in appetite or weight, sleep, energy, and psychomotor activity. The cognitive changes include feelings of worthlessness or guilt; difficulty in thinking, concentrating, or making decisions; and recurrent thoughts of death or suicidal ideation, plans, or attempts. Loss of interest or anhedonia, the inability to experience pleasure, is another cardinal feature. Although not necessary for a diagnosis of a major depressive episode, a depressed mood is usually present. The mood in a major depressive episode is often described as depressed, sad, hopeless, empty, discouraged, or down. The depressed mood is not always acknowledged or recognized by the patient and may need to be inferred from the patient’s demeanor or facial expression. The affect is revealed by the slowed and hypophonic speech produced (Greden et al. 1981). “Facial masking” with little or no facial muscle response to emotional stimuli is often seen (Schwartz et al. 1976). The posture is frequently bowed, steps are shortened, and there is a general lack of spontaneous activity (Kupfer et al. 1974). In children and adolescents, an irritable mood rather than a sad mood may be present. Individuals with major depressive episodes may also demonstrate other emotional states including irritability, anxiety, phobias, obsessive ruminations, and excessive worry, in particular about physical complaints.

The depressed mood seen in individuals with dysthymic disorder differs little from that found in major depressive disorder, except in the number and duration of the associated cognitive and vegetative features. The DSM-IV mood disorders field trials (Keller et al. 1995) suggested that cognitive symptoms are more characteristic of dysthymia than vegetative symptoms are. The depressed mood found in dysthymic disorder is typically described as sad or “down in the dumps” and is chronic (at least 2 years in duration).

The depression in an adjustment disorder with depressed mood is a response to an identifiable psychosocial stressor but is not severe enough to meet criteria for another Axis I disorder. The dominant features include a depressed mood, tearfulness, and feelings of hopelessness.

### Clinical Vignette 2

A 35-year-old woman presented to the outpatient clinic. She appeared disheveled with stains on her clothes, sullen, and tearful. She sat in the chair with a slumped posture, at times looking down at the floor. Her speech was of a normal rate and tone. She appeared to be sad. Her affect during the interview was flat and constricted but reactive and appropriate. She displayed a full range of affect. These clinical observations of her affect and the following interview provided a subjective report of her emotional state.

**Interviewer:** What brought you to the clinic?

**Patient:** I feel weak, my stomach hurts.

**Interviewer:** What is your mood like?

**Patient:** I’m nervous.

**Interviewer:** Do you mean you are anxious or sad?

**Patient:** Sad, very sad.

**Interviewer:** How long have you been this way?

**Patient:** A long time.

**Interviewer:** How long have you been this way?

**Patient:** Two months.

**Interviewer:** How long have you been this way?

**Patient:** Days, weeks, months?

**Interviewer:** Two months.

**Interviewer:** So, you didn’t always feel this way.

**Patient:** Oh, no! Thank goodness no [with a chuckle].

**Interviewer:** How about now, in the last 2 months?

**Patient:** Most of the time I’m down, but there are times I feel better, particularly when I have company.

**Interviewer:** How sad do you feel? Is this the worst that you have ever felt?

**Patient:** I’m not sure what you mean.

**Interviewer:** Well, let’s say 1 is your worst and 10 is when you are feeling the best.

**Patient:** I guess I’m a 2. I’m not yet to the point of killing myself.
Emotional Expression of Euphoria

Euphoria is defined as intense elation often associated with feelings of grandeur. Euphoria, elation, exultation, and ecstasy are synonyms that describe an exceedingly pleasurable mood. These emotions can be a part of normal experience. Euphoric states are achieved during sexual pleasure, when one is in love, after achieving a long-sought goal, or just when life is going well. Religious experiences can also result in feelings of euphoria. When euphoria goes beyond the range of normal experience and becomes a psychiatric problem, mania or hypomania is present.

Euphoric mood states may be induced by numerous drugs, neuroleptical conditions, systemic medical disorders (Table 36–15), and psychiatric illnesses. The psychiatric conditions in which euphoric mood predominates are among the DSM-IV-TR mood disorders: bipolar I disorder, bipolar II disorder, cyclothymic disorder, bipolar disorder NOS, mood disorder due to a general medical condition, substance-induced mood disorder, and mood disorder NOS. Euphoria is also characteristic of schizoaffective disorder, bipolar type. Euphoric mood states are characterized as being either a manic episode or a hypomanic episode.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

The elevated mood of a manic episode is described as euphoric, unusually good, cheerful, or high. It is viewed as excessive and may seem to have an infectious quality. The quality of the mood is expansive with indiscriminate enthusiasm for interpersonal, sexual, and occupational interactions. Speech during a manic episode is pressured, loud, rapid, and difficult to interrupt. Lability and irritability of mood are often seen in manic episodes. The expression of the euphoric mood seen in a hypomanic episode is similar to that of a manic episode; however, it is not as severe and consequently does not result in psychotic features, hospitalization, or marked impairment in social or occupational functioning as seen in manic episodes.

Emotional Expression of Apathy

Apathy is characterized by a dulled emotional tone associated with detachment or indifference. The apathetic individual is often described as a “bump on a log.” Abulia refers to conditions of severe apathy, the loss of will to act, and inability to make decisions or to set goals. This differs from avolition, one of the negative symptoms of schizophrenia, in that the wish to do something is present, but the desire is without energy (Edgerton and Campbell 1994). The abulic patient may be immobile, be virtually unresponsive, or appear even comatose. Harry Stack Sullivan introduced a psychodynamic explanation for the existence of apathy as an emotion expressed in personality development (Mullahy 1952). He considered apathy an early security operation, a means of reducing awareness and susceptibility to interpersonal tension and of dealing with anxiety.

Bleuler (1924) pointed out that apathy to the extent that there is no affect probably does not even occur in psychoses or in the most severe organic brain injury. Lack of interest in almost everything that occurs is seen among some individuals with schizophrenia and dementia. DSM-IV-TR includes negative symptoms as a characteristic of schizophrenia. Affective flattening, alogia, and avolition may all characterize the emotional expression of apathy (Table 36–16). Individuals with severe major depressive episode may also present as apathetic, because they may not be able to discern their own feelings. Frontal lobe syndromes involving the orbital regions typically result in unresponsiveness to environmental stimuli. Individuals with frontal lobe syndromes often lack initiative and are unmotivated and disinterested in their daily activities. Apathy is also characteristically seen in Alzheimer's disease, other dementias, delirium, Huntington's disease, Korsakoff's syndrome, and Parkinson's disease. Individuals with right hemisphere strokes compared with left-sided lesions have a greater risk of presenting with apathy (Marin et al. 1995).

Emotional Expression of Hostility, Anger, and Rage

Hostility, anger, and rage are aggressive emotions. These emotions are characterized by heightened vigilance in response to a sense of threat. Often there is a tendency to act and engage the threatening stimulus. There is heightened physiological tone in preparation for a behavioral response. This behavioral response varies with societal and cultural norms and ranges from the adaptive-constructive response of assertiveness to the destructive response of violence (Yager 1989).

Individual differences in expressing and experiencing aggressive emotions may be cultural, developmental, and temperamental. An infant's temperament at birth may
mood are not separate entities, although they are often considered as such. Any observable emotion or body feeling from which the psychiatrist makes an inference about affect could also be incorporated into determining the mood (Owens and Maxmen 1979). The important point in the description of emotions in the mental status examination is to obtain both a subjective report and an objective evaluation. It is the patient’s described and observed emotion that allows the psychiatrist to properly distinguish and subsequently make a diagnosis of disorders that are related to anxiety, depression, euphoria, apathy, hostility, and anger.

Pavlov IP (1927) Conditioned Reflexes. Dover, New York, USA.

Mental disorders are syndromes consisting of sets of symptoms. The terminology that psychiatrists use to refer to these syndromes is one of convention. The research that helps define our terminology has limitations and, therefore, describes only a portion of any sample of patients (Becker and Kleinman 1991). The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) and the International Classification of Diseases, 10th revision (ICD-10) present categories for a large number of mental disorders. However, how individuals experience their symptoms and what is described to the physician may not fit easily into phenomenological, nosological systems such as DSM-IV-TR and ICD-10. The brain, in response to mental activity in the person's mind, may express the disorder only psychologically, that is, with thoughts and emotions. The brain also has control over the body via both humoral and neuronal systems and may express the disorder physiologically. Therefore, the consequences of mental distress can be expressed psychologically, along with somatic manifestations, or mental distress can be expressed somatically, with minimal psychological experience.

The environment, culture, childhood experiences, previous experiences with physicians, and the person's family influence the patient's experience of distress. How the patient expresses distress will have a crucial impact on the physician's ability to arrive at an accurate diagnosis. Culture has the most powerful influence on the expression of symptoms (Kleinman 1988). The influence of culture may determine which of the symptoms in a disorder are expressed and how they are expressed. Culture influences the meaning that one attributes to symptoms. The cultural explanations of illness also help define the person's behavior and "sick" role (Ton and Lim 2006). Patients' beliefs regarding the origin of their symptoms, both medical and psychological, have implications in terms of what patients conceal/reveal during the diagnostic evaluation. The outcome of the evaluation diagnostically, i.e., whether the symptoms are diagnosed as medical or as mental, has meaning for the individual, may have legal implications, and may have an impact on the role the person plays in society (Becker and Kleinman 1991). The diagnosis of a "medical" illness carries with it certain rights and privileges, including the reduction of certain responsibilities; however, people with "mental" problems potentially suffer from stigma and prejudice attached to psychiatric disorders. These beliefs influence the patient, his or her family, the patient's physician, and potentially impact directly upon the patient-physician relationship. The ability of a patient to work with his or her physician plays an important role in determining the success of medical interventions. How patients relate to their physicians derives from childhood experiences that result in secure or insecure attachments. Those patients who have difficulty in establishing a working alliance are less likely to adhere to the physician's recommendations (Ciechanowski et al. 2001).

Industrially developed nations, particularly those with Western cultures, are more likely to focus on psychological symptoms as the core manifestations of psychiatric illness; in contrast, somatization is much more the norm in non-Western cultures and underdeveloped countries. The reported prevalence of disorders such as depression and anxiety may vary widely across cultures, depending on the criteria used for the diagnosis. An individual's acceptance of receiving a psychiatric diagnosis, rather than a medical diagnosis for the same set of symptoms, is influenced by the stigma attached to psychiatric disorders in that person's culture. Personal characteristics and cultural beliefs also influence the expression of symptoms in forms that are not somatic and thus are determinants of what information the physician is able to obtain from the patient. The information the physician obtains, and more importantly, the information that remains unknown, influence the accuracy of the diagnostic process.

The powerful role that culture plays is not only a major point of interest of cross-cultural psychiatry but also the one with considerable practical significance. The "culture" of the United States is heterogeneous, reflecting many different points of view regarding physical and mental illness. Immigrants from other countries bring with them their...
cultural views retaining these cultural beliefs, though apparently assimilated. The psychological framework that defines psychiatric disorders for physicians may not be the same to which any portion of a particular population of patients subscribes. Physicians inevitably encounter patients from cultures whose metaphors of distress vary widely. Many patients are likely to present with a variety of physical complaints, particularly to their primary care physicians, and a significant portion of these patients have psychiatric problems (Ormel et al. 1990). In spite of advances in our understanding of the neurobiology of psychiatric disorders, mental illness remains associated with stigma in the US. Despite the importance of mental disorders in detractions from the overall well-being of patients, the accurate diagnosis of these disorders in primary care settings is quite low (Ormel et al. 1990, Sherbourne et al. 1994). General practitioners are less likely to recognize generalized anxiety disorder when patients present with a physical complaint (Munk-Jørgensen et al. 2006).

Physical signs and symptoms may be magnified or minimized depending on the patient’s personality traits or personality disorder. Personality traits may be exacerbated by a medical illness limiting the person’s ability to handle the stress of being in the sick role. These patients may be clingy/dependent when first encountered, only to become angry/hostile when their physicians withdraw from the unremitting neediness. They may communicate their needs through vague physical complaints, while being uncooperative with the medical evaluation. This may compromise the delivery of medical care in a variety of ways (Muskin and Haase 2001). Physicians experience them as “difficult patients” and avoid contact as much as possible, compounding the problem with the patient. At times, the physician may feel compelled to order many procedures or obtain many consultations (not psychiatric) to placate a patient (Mozian and Muskin, in press). In the evaluation of a patient, one must be mindful of the interplay of culture, personality, family influence, and previous experience to better understand if this set of signs and symptoms is a consequence of mental distress expressed psychologically with somatic manifestations or mental distress expressed somatically with minimal psychological experience.

Evaluation of Physical Signs and Symptoms
All patients presenting with “psychiatric” symptoms require a careful and complete physical examination. Routine blood tests should include a complete blood count; determination of serum glucose and electrolyte levels; testing for hepatic, renal, and thyroid function; and testing for sexually transmitted infections. Urinalysis, an electrocardiogram, and a chest radiograph should also be obtained. Neuroimaging is an important diagnostic tool to exclude neurological disorders that may initially present with psychological symptoms. A thorough medical history and a family history of medical illness are crucial components of an adequate psychiatric evaluation. In many cases, the psychiatrist is the only physician who obtains a history from the patient leading to counseling and testing to determine the patient’s HIV status.

Psychiatric disorders can alter the way in which patients manage their health and health care. Patients with depression are at risk for metabolic disturbances secondary to anorexia. Of particular importance is dehydration, which may alter serum electrolytes and magnify some of the side effects of antidepressant treatment, such as orthostatic hypotension. Patients who are admitted with dehydration or who have been found at home in a dehydrated and malnourished state should be screened for depression. Agitated states, such as mania and schizophrenia, place patients at risk for a variety of medical problems. Increased motor activity for days or even weeks can affect joints and can lead to malnutrition and exhaustion. Inattention to intercurrent medical problems because of impaired judgment and agitation may lead to severe infections that would otherwise be easily treated.

Patients with mood disorders, both depressed and bipolar, as well as patients with a broad range of psychoses, may become noncompliant with medication regimens to which they were previously adherent during exacerbations of the psychiatric disorders. Failure to take necessary medications or follow a restricted diet worsens the underlying medical disorder. Primary care physicians may not be aware of the patient’s psychiatric disorder and thus cannot understand why the patient has become nonadherent.

Physical Manifestations of Anxiety
Anxiety is an internal feeling state of fear in which the person does not know the cause of the fear. It is not a pleasant experience. Research has shown that anxiety at low levels of intensity can be motivating and increase performance (Yerkes and Dodson 1908). Increased levels of anxiety result in greater degrees of discomfort and dysfunction. At all levels of intensity, anxiety is commonly associated with physical symptoms. Some anxiety disorders such as panic disorder are always associated with physical symptoms. There is no organ system that is immune from physical symptoms associated with anxiety. The differential diagnosis for patients who have symptoms thought to be related to anxiety must always include a medical condition (Table 37–1).

As a rule, symptoms that fall into the following four categories should be considered as potentially resulting from anxiety:

1. symptoms that have persisted over long periods of time;
2. symptoms that change character over time but do not worsen in intensity;
3. repeated negative evaluations searching for a medical illness that would explain the symptoms;
4. symptoms that do not match the description of known medical conditions.

Difficult-to-diagnose medical conditions pose a challenge for the physician, as many of these patients may be misdiagnosed as having psychiatric rather than medical conditions (Hall 1980). This should not result in patients being misdiagnosed with psychiatric disorders rather than medical disorders. Patients with panic disorder typically present to primary care physicians for medical evaluation. They may complain of chest pain, shortness of breath, a variety of abdominal symptoms, headaches, visual disturbances, and so on, and are convinced that their symptoms are indicative of a serious medical disorder (Sheehan and Sheehan 1982). A common presentation, particularly in the emergency department, is a young person with complaints of chest pain and shortness of breath. The symptoms suggest to the person that she/he is having a heart attack. The intensity of
the symptoms, and the patient’s conviction that something must be wrong medically to generate such discomfort, often convince the patient’s physician that there must be a medical cause for these symptoms (Muskin 1985). This leads to an exhaustive, but negative, medical evaluation. The negative workup often results in the patient being told, “Nothing is wrong.” Telling the patient that “nothing is wrong” is not reassuring. There clearly is something wrong as the patient experiences frightening physical symptoms. Teaching physicians to explain that the negative evaluation indicates there is no obvious medical cause for the symptoms is really a positive outcome; however, that information is insufficient for the patient. The physician needs to add that the symptoms may result from, or have been exacerbated by, a psychiatric etiology. Exploring that etiology is as important for the patient’s well-being as any “medical” evaluation. Indicating a willingness to continue to treat the patient along with a psychiatrist prevents the patient from feeling either abandoned by the primary care physician or stigmatized by having a “mental disorder.”

Patients with anxiety often complain of feeling weak, having fatigue even with normal duration of sleep, and becoming exhausted with minimal exertion. Patients may offer no complaint of feeling anxious and may not appear anxious, or they may complain of feeling anxious regarding their physical symptoms. We separate signs (the observable phenomena or laboratory results) from symptoms (subjective experiences that patients offer as their chief complaint). The signs of anxiety are irritability, pacing, or restlessness during the history or physical examination. There can be a cold, clammy feeling to the skin and a fine tremor. In cases of severe hyperventilation, a patient may demonstrate Chvostek’s sign, which is tetany (tonic muscular contractions, tremors, and parasthesias) caused by a low serum calcium level resulting from the hyperventilation-induced respiratory alkalosis. At electrocardiography, a sinus tachycardia may be observed and patients may have elevated systolic blood pressure. A systolic ejection murmur of mitral valve prolapse may be heard in some patients with panic disorder (Gorman et al. 1981), but mitral valve prolapse does not appear to cause panic disorder (Crowe et al. 1982).

Symptoms of anxiety are the subjective experiences that patients offer as their chief complaint. These symptoms commonly affect the cardiovascular, pulmonary, gastrointestinal, nervous, or genitourinary systems. It is not known why one organ system is affected in one patient but not in another; however, patients have varying tolerance for symptoms. People may ignore symptoms in one organ system but focus their attention on symptoms in another system that they find more distressing (Muskin 1985).

Patients may have one, some, or all of the symptoms listed in Table 37–1. This is not an exhaustive list, and patients may complain of many other physical problems. It must always be kept in mind that patients may have both a psychiatric disorder and a medical disorder. A thorough medical evaluation of the patient’s complaint must precede the final decision that the symptoms originate exclusively from an anxiety disorder. It is never appropriate to tell the patient that his or her symptoms are “all in your head.” Every patient deserves to understand that a psychiatric diagnosis

Mr. T was a 20-year-old college senior who had been evaluated medically by several physicians prior to the psychiatric consultation. He complained of nausea and experienced one or two episodes of vomiting. Repeated medical workups were not revealing. His family physician told his parents that Mr. T had a severe psychiatric disorder. He was a straight “A” student and an athlete. Although handsome, he rarely dated. The psychiatrist was able to elicit all the symptoms of panic disorder and a history of repeated panic attacks. The only symptoms that Mr. T cared about were nausea and vomiting. He feared he would vomit on a date or in a public situation and would be embarrassed. Mr. T was successfully treated with desipramine at a dose of 300 mg. Symptom-free, he graduated from college, and easily obtained employment. The fears of a serious psychiatric disorder were not substantiated as he had a successful marriage and a career as an executive who traveled around the world for his company.
refers to a real illness. It is worth keeping in mind that patients with anxiety disorders are significantly more likely to have comorbid cardiac disorders, hypertension, gastrointestinal/genitourinary problems, and migraine compared to patients without anxiety disorders (Härter et al. 2003).

**Physical Manifestations of Mood Disorders**

Mood disturbance, like anxiety, commonly presents with physical symptoms. An unhappy emotion can be a normal reaction to a variety of life events, and most people would refer to this as depression. A sense of bereavement is also a normal response to life events, including the loss of a relationship, the death of an important individual, the loss of a body function, or the loss of a body part. The sadness in these situations may be accompanied by some somatic symptoms, typically a decrease in appetite or some disturbance in sleep. It is not surprising that people experience some alteration of their mood during such circumstances. Sadness, depression, and feeling blue may be experienced in reaction to some physical malady or may be a component of the medical disorder. Some patients have such severe agitation that they do not experience themselves as primarily depressed. Their anxiety is so dramatic that the physician misses the diagnosis of depression. Mixed anxiety and depression is common and should be a diagnostic consideration in anxious patients with any degree of mood alteration.

Many women experience some degree of mood alteration after the birth of a child. A woman may fail to distinguish the progression from postpartum blues into mood disorder because she is sleep deprived, fatigued, and normally occupied by the activities of caring for a newborn. Postpartum depression can be a serious illness, endangering the life of both mother and child. It is not a rare disorder, occurring in approximately 15% of women (O’Hara et al. 1990, Wisner and Wheeler 1994, Gaynes et al. 2005). Women with a history of major depression have a risk of 10–25% of experiencing an episode of postpartum depression (O’Hara 1995, Garvey et al. 1983). Obtaining a history of a prior postpartum depression is crucial as there is a 50% risk of another episode with subsequent births.

As is the case with anxiety, patients with depression often go to their primary care physicians with somatic, not psychological, complaints. Almost five times as many patients with depression spend days in bed with physical symptoms as people in the general population (Wells et al. 1988). Studies using structured psychiatric interviews have shown that the point prevalence of major depressive disorder ranges from 4.8 to 8.6% in primary care outpatient settings. Of adult medical inpatients, 14.6% meet criteria for major depressive disorder (Feldman et al. 1986).

People with depression typically present with complaints of fatigue, insomnia, lack of energy, and poor appetite. Many people continue to go to work and maintain their routine in spite of how miserable they feel. Typically, patients have a medical rationale to explain their physical complaints, such as anemia, vitamin deficiency, or the possibility that they have cancer. In a study performed in primary care clinics around the world, 69% of patients meeting DSM-IV-TR criteria for major depression have a somatic presentation (Simon et al. 1999). Study countries included Brazil, China, France, Germany, Greece, India, Italy, Japan, Nigeria, Turkey, The Netherlands, the UK, and the US. Half of these patients have unexplained medical symptoms (Simon et al. 1999). Physicians in primary care settings see the majority of patients with depression and should always consider a mood disorder in patients for whom the medical evaluation proves unrewarding.

Patients with insomnia are often convinced that their insomnia is the cause of the other physical symptoms that might otherwise be considered as part of a depression (fatigue, aches and pains, anorexia, anhedonia). Sleep disturbance, fatigue, nonspecific musculoskeletal complaints, or multiple complaints in patients seen in primary care settings correlate highly with depression (Gerber et al. 1992). The simple inquiry, “How are you sleeping?” may open the door to complaints otherwise unspoken, and lead to a diagnosis of a mood disorder. In addition, many patients have a variety of vague physical discomforts when they are depressed, such as headaches, backaches, and muscle aches. They may also have gastrointestinal symptoms such as indigestion, change in food preferences, or decreased appetite. In the primary care setting, such complaints may lead to numerous tests that are not diagnostic and are expensive.

In the absence of targeted questioning, patients may not talk about decreased interests in usual activities, decreased sexual interest, feelings of low self-esteem, or suicidal thoughts. The alterations in concentration and memory that occur in depression may be concealed because patients fear that the symptoms are indicative of senility. Similar to the patients with anxiety disorders, depressed patients may experience “sadness” about their lack of energy and other physical symptoms, but neglect to mention any other changes in their emotions. Patients may be delusional, but mood-congruent delusions, such as a patient’s intense fear that the physical symptoms are a result of an occult malignancy, may have a surface validity and not seem obviously delusional. Thus, the physical symptoms, and/or the patient’s beliefs about the cause of the symptoms, may delay or prevent the accurate diagnosis of depression.

Severely depressed patients may present with a picture resembling that of a dementia. Slowed thinking, long response time to questions, inability to pay attention, and failure on cognitive testing (typically “I don’t know” rather than an incorrect answer) may convince family and physician that the person has an “organic” problem.

Reliance upon the vegetative symptoms of depression may cause diagnostic confusion in patients with medical illness. Many disease states and/or medical treatments can cause the vegetative symptoms associated with depression such as insomnia, fatigue, anorexia, and weight loss. Although it is understandable that someone might be sad as a reaction to a medical illness, the reasonable nature of the reaction does not rule out the possibility of a mood disorder. Severe indecisiveness, hopelessness, failure to respond appropriately and emotionally to improvement in the medical condition, or dissatisfaction with medical care out of proportion to the norm, may indicate a mood disorder (Cavanaugh 1994). Why some people develop a mood disorder during or after unfortunate life events, such as a serious physical illness or the loss of a significant person, is not yet known. Nevertheless, symptoms of depression such as anhedonia, hopelessness, worthlessness, indecisiveness, and insomnia should be sought out as they have been shown to be predictors of death in hospitalized medical patients (Furlanetto et al. 2000).

Section V • Manifestations and Assessments
Mythological Characteristics of Patients

How a patient copes with illness may be as challenging for the physician as the illness itself (Gazzola and Muskin 2003, Groves and Muskin 2005).

Psychiatric patients (i.e., patients who have a psychiatric diagnosis known to their physicians) may have medical disorders that are not diagnosed because the presenting symptom appears to be mental (so-called functional) rather than physical (so-called organic). This is the reverse of the situation described in the sections on the physical manifestations of anxiety and of mood disorders, in which patients present with symptoms that are taken to be the result of a general medical condition, rather than the somatic manifestations of a psychiatric disorder. Hall (1980) notes nine mythological characteristics of patients who are diagnosed as having functional medical complaints (Table 37–2). If the physician holds these myths to be axiomatic truths, this belief will impede the appropriate evaluation of the patient’s underlying or concomitant medical disorder. The nine characteristics in Table 37–2 are a reminder that every clinical situation must be fully evaluated, no matter how obvious it seems that the complaints are functional.

In a review of 658 consecutive psychiatric outpatients, careful medical evaluation revealed that 9.1% of the psychiatric cases had a medical illness that produced the psychiatric symptoms (Hall et al. 1978). Depression, confusion, and anxiety were the most common presentations. Cardiovascular and endocrine disorders were most commonly the cause

### Physical Disorders Causing Secondary Mental Symptoms

Numerous medical disorders have behavioral components, such as the mood disorder that occurs with many different endocrine disorders or the psychiatric symptoms that may occur with a disorder such as systemic lupus erythematosus. Many different aspects of the experience of being physically ill can exert either a psychological and/or a physiological effect on patients. A patient’s mental status or a patient’s ability to experience and express emotion may change as a result of the direct effects of a medical condition on the patient’s brain. For example, cerebrovascular accidents have a direct effect on brain tissue and thus on mental function. Conditions that alter blood flow to the brain, such as arrhythmias, hypotension, or vascular disease, also alter cognition. Systemic disorders including sepsis, disturbances in electrolyte and glucose metabolism, and a variety of intoxications all have effects on the brain and thus influence thinking and emotion. Neurological problems, as well as substance overdose or withdrawal, can present with behavioral dyscontrol and perceptual disturbances that may look like a psychotic episode.

Medical illness also has global effects on the body. There may be changes in the person’s appetite, sleep, or libido. From a psychodynamic perspective, medical illness has a regressive effect on the psychological functioning of the patient such that she/he may be less able to cope with the demands of the current situation (Strain and Grossman 1975). Regression can be understood as an alteration in the coping skills employed by the individual reflective of an earlier stage of psychological development. Patients may also have psychological reactions, such as anxiety or depression, in response to their alterations in cognitive function. How a patient copes with illness may be as challenging for

### Clinical Vignette 2

Mr. C was referred for a psychiatric evaluation while an inpatient on a medical ward because his primary care physician was convinced that the patient had a depression. Mr. C complained of fatigue, sadness, and inability to cooperate with physical rehabilitation following a recent hip replacement. He had been treated with a serotonin reuptake inhibitor before admission without success. Although unhappy about his inability to regain full use of his leg, and afraid he would not be able to dance at his daughter’s wedding, he had no other symptoms of depression. The psychiatric consultant discontinued the antidepressant. Mr. C had “heavy” eyes and blurred vision that resulted in an ophthalmology consultation. He had a positive edrophonium (Tensilon) test and was diagnosed with myasthenia gravis. This eventually led to surgery for a thymoma. The subsequent hospital course was extremely difficult. After several weeks, Mr. C became tearful, anxious, and severely indecisive about his care. He was unable to sleep. In spite of continued improvement medically, he was consistently fearful that he would die. After 2 weeks of treatment with a serotonin reuptake inhibitor for his depression, and a benzodiazepine to treat his insomnia, Mr. C felt less depressed. He was no longer tearful and was able to engage actively in decisions regarding discharge planning. Mr. C left the hospital walking, smiling, and ready to enjoy his daughter’s wedding.

### Clinical Vignette 3

Ms. P, a 38-year-old successful businesswoman and mother of two teenagers was seen in psychiatric consultation 2 days after the removal of a pheochromocytoma. She described feeling sad and gave a history of several years of intermittent episodes of palpitations, headaches, tremulousness, and flushing. Her physician had told her she was overwhelmed by being a “supermom” and anxious because of chronic marital problems. Ms. P was told to see a psychotherapist, a recommendation she did not follow. She would not have consulted an endocrinologist, and would not have had successful surgery for her pheochromocytoma, had a friend not heard a radio program about medical disorders that cause anxiety-like symptoms.
of the psychiatric symptoms. Infections, pulmonary disease, gastrointestinal problems, hematological disorders, a variety of central nervous system disorders, and cancers were also found as the actual etiology of the “psychiatric” symptoms.

No convenient system exists to connect any one medical disorder with a particular set of psychiatric symptoms. Disorders such as systemic lupus erythematosus, acquired immunodeficiency syndrome, and pancreatic carcinoma regularly have a psychiatric presentation, particularly symptoms of mood disorders. This is of special importance in patients with acquired immunodeficiency syndrome (Perry and Tross 1984, Dilley et al. 1985, Navia et al. 1986a, 1986b, Johannet and Muskin 1990). Patients with hallucinations, especially visual hallucinations, should receive a full workup to exclude a medical etiology for their symptoms. Another worthy consideration in patients with symptoms of anxiety or depression is a subclinical thyroid disorder (Cooper 2001, Singer et al. 1995).

Clinical Vignette 4

A 44-year-old executive was hospitalized for the treatment of ophthalmic herpes. When seen for a pain consultation, she was found to be agitated and “psychotic.” The psychiatrist consulted noted that she had a fluent aphasia. The agitation was actually her distress regarding her sudden inability to communicate, and not from a psychosis. The psychiatrist recommended a neurological consultation. A CAT scan of her head revealed several lesions scattered on the left side of her brain. As a glioblastoma with satellite lesions was a strong diagnostic consideration, a brain biopsy was performed. This procedure led to a diagnosis of toxoplasmosis. The patient gave no risk factors for human immunodeficiency virus infection except for unprotected sex several years before the admission. She tested positive for human immunodeficiency virus. Her “psychosis” cleared with treatment of the opportunistic infection and the resolution of the aphasia.

Clinical Vignette 5

Mrs. O complained of feeling sad, with anorexia, weight loss, fatigue, and periods of tearfulness. These symptoms began following the physical and cognitive decomposition of a family member who required placement in a nursing home. She had retired from a successful career and noted she had never been physically ill in the prior seven decades of her life. She was reluctant to take any form of medication, but as her symptoms increased, she agreed to take a serotonin reuptake inhibitor. She also agreed to have a medical evaluation that revealed a low TSH with a high normal T4. Her response to antidepressant treatment was incomplete until she was treated for the subclinical hyperthyroidism by radioactive iodine. Following that treatment, she remained euthymic without antidepressant therapy.

Intoxication and Withdrawal

When the clinical presentation is one of anxiety, agitation, confusion, paranoid ideation, or psychosis, it is important to consider that the patient is intoxicated by any one of a variety of substances. Conversely, the same presentation can occur in patients in withdrawal from a substance. Patients who are intoxicated have positive serum or urine toxicologic test results, whereas patients who are withdrawing typically have none of the substances in their blood or urine. However, in cases of chronic substance abuse, particularly with alcohol, patients may have serum levels of alcohol that, for them, are too low to prevent withdrawal. When this fact is not recognized, the patient’s behavior can be a source of confusion in the diagnostic evaluation. The physician may not realize that the anxious patient is actually delirious. Patterns of substance abuse vary considerably, and many patients use more than one substance simultaneously. In complex cases, it is worth considering the possibility that the patient is withdrawing from a substance that was not included in the history (Muskine et al. 1998).

Clinical Vignette 6

An 87-year-old woman was admitted to the neurology department with confusion and agitation. She was not able to give a coherent history, but her family reported that she had been a department store executive and that she was devoutly religious. Her medical evaluation was completely negative except for the change in her mental status. During the next day her agitation worsened. Her daughter reported that her mother had several large shopping bags of prescription medications in her bedroom, undoubtedly accumulated over many years. In her delirious state, the patient denied taking any of these medications except for “my Centrum at bedtime.” The psychiatric consultant suggested that Centrum (a multivitamin) might actually be Centrax (prazepam, a benzodiazepine with a long half-life). The psychiatrist suggested that the patient was in a benzodiazepine withdrawal delirium. An intramuscular administration of lorazepam brought the delirium under control, with rapid improvement in the patient’s agitation. The patient was detoxified using oral lorazepam during the next week. She remained fully oriented and without confusion. Her family removed her collection of medications before she returned home.

Agitation

Many medical disorders may have psychiatric presentations with either depression or anxiety symptoms. There are also patients who present with symptoms that are mixtures of agitation and depression or mixtures of lethargy and anxiety. In some clinical situations, a patient’s agitation may be difficult to differentiate from anxiety. Anxiety is typically a feeling that remains throughout the day, with increases or decreases in the intensity of the feeling in the setting of a clear sensorium. Confusion, disorientation, and a fluctuating level of consciousness often accompany agitation. Some patients demonstrate a pattern of agitation alternating with sedation. Of particular diagnostic importance are symptoms in an elderly patient that are thought to represent anxiety, but the patient is actually suffering from a delirium. Delirium may be the presenting picture in elderly patients and may be the consequence of a variety of metabolic, hemodynamic, infectious, and pharmacological factors. The possibility of an anticholinergic delirium should always be entertained for a geriatric patient who seems anxious. Numerous medications that are commonly prescribed for geriatric patients have anticholinergic side effects. Although the potency of the anticholinergic effect...
for any one drug may be small, the additive effects of several drugs can produce an anticholinergic delirium (Tune et al. 1992). Over-the-counter (OTC) analgesic agents that are “PM” contain diphenhydramine, which has anticholinergic properties. Patients taking several pills daily may present with agitation that is actually an anticholinergic delirium. A variety of medications including benzodiazepines, dopaminergic agents, narcotics, and OTC/prescription hypnotics have the potential to cause delirium, particularly in the elderly (Medical Letter 2000, Inouye 2006). Patients with delirium may be misdiagnosed with anxiety if they are agitated, or may be misdiagnosed with depression if they have a hypoactive delirium.

A complete evaluation always includes an investigation of the patient’s medications. This includes currently prescribed medications, ones the patient still possesses from prior prescriptions, and OTC medications. Many patients use alternative therapies but do not inform their physician of the treatment (Eisenberg et al. 1998, Kenny et al. 2001). In addition, many people use an alternative therapy without consulting a practitioner of complementary and alternative medicine (Eisenberg et al. 1998, Kenny et al. 2001). Thus, the investigation of a delirium should also include an inquiry regarding the use of herbs, neutraceuticals, and other alternative medicines (see Chapter 108). Psychiatric symptoms can be caused by such a large number of medications that it is always worthwhile to consult a reference when a patient is taking a medication new to the physician (Medical Letter 1993, 1998). Steroids, antihypertensive medications, H2 blockers, isotretinoin, and interferon should always be considered as a causative factor if the patient develops depression during treatment with one of these agents (Wholley and Simon 2000, Wysowski et al. 2000, Musleman et al. 2001). See Tables 37–3 and 37–4 for guides regarding medical disorders that may present with symptoms suggestive of a depression or of an anxiety disorder.

### Physical Symptoms without Known Etiology

Although physical presentations of psychiatric disorders are a common occurrence, some psychiatric disorders involve complaints of physical problems, without an underlying anxiety disorder or affective illness. These patients are people for whom psychological matters are expressed via their bodies. It is estimated that as many as 10% of all medical patients have no medical illness but still receive a diagnostic evaluation and medical treatment (Ford 1986).

Patients who have either somatoform or factitious disorders assume the rights that accompany the role of the physically sick without the organic pathology on which the role is based. The individual is presumed to be weakened by the underlying disease. In being sick a person is thus excused from everyday responsibilities, without being blamed and penalized. A sick person is not expected to recover by force of will alone and can expect to be cared for by others. The “sick” role does carry with it certain obligations. The person who claims to be ill is expected to seek medical attention in order to discover the cause of the symptoms. She/he is expected to accept appropriate treatment for the malady. There is an expectation from family and physicians that the “sick” person desires to return to being well.

When people become ill for physiological reasons, the sick role is imposed upon them involuntarily. What is unique about patients with a somatoform or factitious disorder, and is often extremely frustrating for their physicians, is that these patients take on the sick role for psychological reasons. The underlying “motivation” that results in the person’s complaint of a somatic problem may be unconscious, or it may be part of a conscious plan to create or fake a medical problem.

Patients with somatizing disorders do have an illness; they experience themselves as not being well. This experience impairs their lives. They may or may not have a disease, that is, there may or may not be an objective evidence of organic impairment. Although people may use somatic symptoms for either conscious or unconscious gain, it is possible that both a psychiatric illness and a medical disease are present. Some patients have clear evidence of disease but claim not to have an illness (i.e., they do not have an experience of being ill) and they are noncompliant with the treatment. Some patients of this group have psychosis, delirium, or dementia as the source of their denial of illness. There may be a small group who has maladaptive denial of physical illness (Strauss et al. 1990, Muskin et al. 1998a).

Somatic expression of psychological problems occurs commonly and typically is not severe enough to lead to medical attention. The queasy stomach before an examination and the headache in anticipation of or during an undesirable activity are well known. For some people, psychic

experiences are readily translated into bodily experiences and such individuals seek treatment for their physical ailments unaware of this psychological mechanism.

Physicians may play a role in the continuation of the psychiatric disorder by accepting the patient’s complaints without a thorough evaluation of the patient’s history, and without obtaining a detailed history of prior treatment. Physicians are often unaware that the patient’s somatic complaints are both a metaphor for psychic suffering and the patient’s intense need to be taken care of by someone. If the patient’s psychology is not understood, no attempt can be made to understand the kind of help the person requires. In this setting, the patient is compelled to continue to complain of physical problems. A physician may find it impossible to believe that the patient is unaware of what appear to be obvious psychodynamic issues. The physician’s anger or neglect may motivate the patient to seek “better” care, which often translates into consulting a different medical doctor, not pursuing psychiatric treatment.

There is limited time available during any clinical encounter and thus it is impossible to review every symptom about which a patient complains. Any physical complaint could be a “real” medical disorder or a symptom of a somatoform disorder. There are certain “qualities” about how a patient with somatoform disorder presents that are worth reviewing. A patient with a somatoform disorder frequently will consult several physicians simultaneously or in rapid sequence. In contrast to the average medically ill patient who tries to give an adequate history but often leaves out many details, a patient with somatoform disorders describes symptoms in exquisite detail, including dates of onset of the complaints, the character of the symptoms, and the precipitants of the symptoms. Such patients often bring the physician the results of previous laboratory and physical examinations. Although the diagnostic evaluation of the complaints typically does not yield positive findings, there are some patients who have a medical disorder that is exacerbated by a somatoform disorder. In these situations, positive physical findings emerge during the workup. One clue to the physician in such cases is that the patient’s complaints exceed what would be expected from the physical or laboratory findings. In other cases, physical or laboratory abnormalities initially lend support to the patient’s complaints but are eventually found not to be etiologically related to the presumed illness.

The manner and extent to which a patient manifests physical symptoms reflect childhood experiences and personality characteristics. An estimated 30–60% of patients in primary care settings complain of symptoms that have no medical basis (Kirmayer and Robbins 1991). The term somatization describes the development, persistence, and preoccupation with unexplained medical symptoms. The establishment of a link from childhood trauma to adult somatic preoccupations has been an attempt to explain the phenomenon. Attachment styles develop early in life, dependent upon interactions between children and their caregivers. Such styles of attachment impact on how individuals expect others to behave, especially during times of dependency, and particularly with people upon whom the person depends for support and advice, i.e., the physician (Stuart and Noyes 1999). The attachment style has a positive or negative influence on how a patient will interact with the physician. People with secure attachment styles experienced reliable caregiving as children, have positive views of the self and others, and can depend upon others comfortably. Insecure attachment styles result from rejecting or traumatic experiences from caregivers. These people have negative views of the self and others. They wish to be close but fear rejection, oscillating between behaviors of approach and avoidance. It is obvious how differently people with these two styles of attachment will behave with physicians. Childhood trauma fosters insecure attachment styles that influences adult levels of somatization in women (Waldinger et al. 2006). Trauma in childhood does not predict an insecure attachment style in men, for whom childhood trauma and attachment style are important independent predictors of adult somatization (Waldinger et al. 2006).

In conversion disorders, patients present with dysfunction of systems typically under voluntary control, such as the motor system, or have symptoms involving the special senses. Patients may have seizure-like symptoms without any evidence of a seizure disorder or may have confirmed electroencephalographic findings that do not correlate with the symptoms. DSM-IV-TR does not require that there be an unconscious conflict that is expressed via the physical dysfunction, but there must be an evidence of a precipitant for the symptoms. The symptoms are often notable for lacking anatomical validity; for example, glove anesthesia of the hand is not in keeping with the innervation of the hand. The symptoms do have causality that is logical from a psychological and symbolic perspective. The patient who is “blind” may have a need not to “see.” Coming to an understanding of the precipitant for the disorder through careful questioning, sometimes aided by hypnosis, may be of value in the resolution of the symptoms. An interview using amobarbital (Amytal) should be considered as a second choice given the higher degree of risk. Some physicians may find it impossible to believe that patients who have a conversion disorder are not aware that their psychology is the “cause” of the symptoms.

Patients with conversion disorders are not necessarily hysterical in demeanor. Whereas some patients may seem unnaturally calm about their malady, a phenomenon known as la belle indifférence, patients may also present with extreme distress caused by the sudden alteration in their physical functioning. The spectrum of intentionality in patients with medically unexplained motor or sensory symptoms or deficits runs from conversion to malingering. Conversion is unconscious and yields psychological gains that are outside the person’s awareness. This must be differentiated from malingering, which is entirely conscious and for the purpose of more readily apparent external incentives.

In somatization disorder, formerly known as Briquet’s syndrome, patients have multiple complaints that have persisted for many years and have resulted in medical treatment(s). Patients may have a history of numerous surgical procedures and of taking many different medications. To fulfill the diagnostic criteria, patients must have complaints involving multiple organ systems and a history that begins relatively early in life, that is, before the age of 30. People with somatization disorder suffer greatly from their constant attempts to obtain treatment. They are at risk of becoming physically dependent on prescribed medications such as narcotics. They may also suffer serious adverse effects.
A psychiatric consultation was requested for Ms. H, a 33-year-old woman who was admitted with paresthesia of the right hand. Her symptoms had developed slowly during the previous day, and she had a history of a stroke 5 years prior to this admission. The patient had a history of taking oral contraceptives, and was overweight, both considered by her doctors to be risk factors for a stroke. Ms. H was tearful about the sudden change in her physical condition and expressed concern about how her mother would manage the care of her 6-year-old son. Further questioning revealed Ms. H's guilty feeling that an angry encounter with her ex-husband might have precipitated this stroke. Her belief was that she should never lose her temper. She also revealed that she went to church daily, prayed often, and occasionally “spoke in tongues.” She was hypnotized during the consultation and was highly hypnotizable (Grade 4) using the Hypnotic Induction Profile (Spiegel 1973, Spiegel and Spiegel 2004). While in the trance, state she talked about having the wish to punch her ex-husband during the argument. Prior to the cessation of the trance, Ms. H was given the suggestion that she would have greater use of her hand and that her strength would progressively increase over the next day. Ms. H had a complete recovery the next day and was able to use her hand without difficulty. She was referred for outpatient psychotherapy to resolve the difficulties with her ex-husband, with whom she had continued contact because of their child.

Clinical Vignette 7

An adequate dose of pain medication often involves the need to use an analgesic, antidepressant, psychotherapy, or a combination of these modalities. Physicians who are not well trained in the use of oral and parenteral narcotic analgesics often encounter a problem that results in patient-physician discord. Many physicians harbor an unsubstantiated fear of causing narcotic addiction, in spite of the evidence indicating a low incidence of iatrogenic addiction (Perry 1984). It is no surprise that the inadequate treatment of pain with narcotic analgesics is a well-documented phenomenon (Marks and Sachar 1973, Sriwatanakul et al. 1983, Kanner and Foley 1981). Inadequate treatment of pain can result in exactly what the physician fears, that is, drug-seeking behavior. As the patient realizes that the pain will not be alleviated because the medication will not be given in adequate doses or frequently enough, she/he begins to utilize manipulative techniques to obtain narcotic analgesics (Weissman and Haddox 1989). The failure to recognize that a patient is not being adequately treated for pain can result in anger at the physician to the point that the patient may want to leave the hospital in spite of the medical consequences (Albert and Kornfeld 1973).

The fear of being ill can reach such proportions that it causes great suffering in the absence of any medical disorder. In hypochondriasis, patients persist in the belief that they are or will become ill, and complain of symptoms for which no medical cause can be found. Their fears of illness endure despite medical evidence to the contrary. The fear is not delusional, that is, the person can consider the possibility that he or she is not ill. The patient’s fear of having an illness should not occur only while experiencing a panic attack, and the fear must last for a period of at least 6 months. Transient fears of having an illness may occur in stressful settings, but this is not hypochondriasis, that is, medical students often fear having the illness that they are studying at

Clinical Vignette 8

Ms. A consulted a psychiatrist because of feelings of depression, anxiety, and a history of difficulties in relationships with men. She had an overwhelming fear that she had acquired immunodeficiency syndrome but had no physical symptoms with the exception of fatigue. Although she could consider the possibility that she was not infected, she believed her sexual history had exposed her to the virus. At the age of 28 years, she had sexual experiences with nine men. The idea of being tested to rule out acquired immunodeficiency syndrome was too frightening because she was convinced that she would test seropositive, and she thus refused to have an HIV test. Treatment of her depression with fluoxetine, and psychotherapy focused on her overstimulating relationship with her father as a little girl resulted in complete disappearance of her fears. She started a relationship with a man and, when appropriate, recommended that they both be tested for human immunodeficiency virus before becoming sexually involved. They both tested negative and began a sexual relationship. There was no return of her ruminations about HIV infection. The couple married and there was no return of the hypochondriacal symptoms during a postpartum depression (requiring antidepressant treatment) after the birth of her first child.
the moment. This fear dissipates when the person reads the next chapter in the medical text. Patients with hypochondriasis have a high degree of psychiatric comorbidity, particularly mood and anxiety disorders (Barsky et al. 1992). Hypochondriacal patients without other Axis I disorders appear to have a lifestyle of worrying about their body, misinterpreting normal bodily experiences as signifying illness, and increasing their discomfort by focusing on their physical experience. These patients are different from the individuals who develop hypochondriasis in response to a life stress or develop it secondary to another physical disorder. Following treatment for a malignancy, some patients may have symptoms of hypochondriasis, checking for lumps, worrying about a cough or bleeding hemorrhoids. These worries may persist until the patient has reached one of the significant milestones of survival (e.g., 5 years).

Body dysmorphic disorder is a preoccupation with a defect of physical appearance in an individual who has a consensually normal appearance. This bodily defect may be imagined or it may be an exaggeration of an actual but insignificant physical attribute (Phillips 1991). Patients who have anorexia nervosa, for example, someone who regards his or her body as excessively fat in spite of a thin appearance and restricted caloric intake, are not included in the body dysmorphic diagnostic category. The disorder was previously termed dysmorphophobia, and patients with such beliefs were described by Morselli more than 100 years ago (Phillips 1991). Patients’ preoccupation with their “deformity” can result in withdrawal from social engagement, repeated consultations with physicians, and attempts to correct the imagined defect with plastic surgery or cosmetic maneuvers. Individuals with delusional beliefs about a physical defect are diagnosed as having delusional disorder; somatic type. However, it may be difficult to make this distinction (Thomas 1985). Treatment of patients diagnosed with body dysmorphic disorder using antipsychotics has not been particularly successful. It has also been argued that the distinction between body dysmorphic disorder and obsessive-compulsive disorder may be blurred in some patients (Tynes et al. 1990).

Clinical Vignette 9
A 50-year-old woman was brought to the hospital by her partner with complaints of confusion, memory impairment, and amnesia. The patient left her home following an argument with her partner had not returned home the night before the admission. Her partner reported that the patient had gone to move her car. There were no signs of physical trauma but the patient was missing all of the jewelry she had worn the night before. An empty bottle of oxycodone was found in her car, but she tested negative for all substance on a toxicology screen. A consultation was requested to evaluate the patient for transient global amnesia thought to be secondary to a presumed sexual assault. The psychiatrist asked that the patient have an MRI that was read as consistent with carbon monoxide poisoning, primarily impacting on the hippocampus.

Factitious Symptoms
Perhaps no group of patients produces more negative reactions in physicians than those who create medical conditions or overtly lie about being ill. When the truth is discovered, such patients are likely to engender anger rather than empathy from their physicians. Physicians commonly fail to distinguish people who have psychological needs that are met by assuming the role of being sick (factitious disorder) from people who feign illness for reasons of personal gain (malingering). There is no physical presentation that cannot be factitiously replicated. Common medical conditions seen in these patients include infection, wounds that do not heal, hypoglycemia, anemia, bleeding, rashes, neurologic symptoms (seizures, dizziness), vomiting, diarrhea, pain, fever of undetermined origin, and symptoms of autoimmune or connective tissue disease. Patients may feign physical illness, psychological illness, or a combination of both (Phillips et al. 1983). When patients feign physical or sexual abuse, there is typically no corroboration for their story. Patients with factitious disorder are more likely to be women than are patients with Munchausen’s syndrome, the most severe form of factitious disorder (Phillips 2001).

There is a risk of patients developing serious medical conditions secondary to what they do in order to induce symptoms, particularly in Munchausen’s syndrome. Patients with factitious symptoms may leave the hospital precipitously when confronted with the discovery of their behavior. Some of these patients may become acutely suicidal when they are confronted. This risk, and how the risk will be handled, should be considered prior to the decision to confront the patient. Overall, confrontation has not been very successful in altering patients’ behavior (Phillips 2001). It is difficult for some nonpsychiatric physicians to comprehend why people would make themselves ill in order to assume the sick role. As psychiatrists, one of our responsibilities is to help our colleagues understand how the sick role confers
special rights including freedom from responsibilities the patient fears she/he cannot fulfill. Such constrictions are of paramount importance to the patient and must be a part of the therapy to allow the person to find adaptive methods of dealing with their psychological needs. This may allow them to give up feigning physical symptoms.

There are also patients who assume the sick role for different kinds of personal gain. These include obtaining relief from financial responsibilities by pretending to be ill, obtaining money from disability insurance, eluding legal proceedings, or avoiding other unpleasant life events. Malingeri is not considered a psychiatric disorder but is a conscious behavior in which the sick role is created to receive external incentives.

Conclusion
Nothing is more rewarding for a physician than solving the diagnostic puzzle of a complex presentation of physical and psychological signs and symptoms, resulting in the patient’s return to health. This challenge exists for psychiatrists and nonpsychiatrists, both of whom see many such patients. Patients report their symptoms and their subjective experience, but it is the physician who puts that information into a differential diagnostic formulation. The physician’s understanding of the role of culture and cultural biases toward mental illness and of the physical components of mood and anxiety disorders results in a consideration of a psychiatric diagnosis. This process occurs even in the absence of the patient’s complaint of psychological symptoms. Instances in which patients’ physical complaints are parts of mood and anxiety disorders may cause diagnostic confusion for physicians who consider only medical diagnoses.

There are patients who insist that they have a medical problem and whose claim is not confirmed by physical examination or laboratory testing. The psychological need to have a physical complaint is the psychiatric disorder for this group of patients. At the other end of this physical–psychiatric continuum are patients, without obvious physical discomfort to suggest a medical condition, who may be misdiagnosed as having a psychiatric disorder because their presentation is atypical, or their complaints are primarily in the domain of how they feel or how they think. Our unique role as physicians enables us to pay attention to all symptoms without the bias of a mind–body dualism. When it comes to the diagnostic consideration of a psychiatric versus a medical condition, we know that it is not either/or but it often is both. Holistic medicine, a term first coined in the 1920s by a South African statesman, has come to be used by practitioners outside of the medical tradition (Muskin 2000). It is clear that the modern practice of medicine, in which we seek to understand and care for the entire patient, is truly what is meant by holistic medicine.

References
To function adaptively means to behave in such a way that one’s attitudes and actions are well matched to the demands and constraints of the external environment and that one’s sense of internal discomfort or distress is minimized. Therefore, by definition, the ability to adapt depends both on the individual’s behavioral repertoire and on the external environment. A person’s capacity for adaptive functioning is so crucial that it has been studied in situations ranging from adaptation to long-term missions in outer space (Eksuzian 1999) to the self-management of life-threatening illnesses such as chronic heart failure (Buetow et al. 2001). This chapter focuses on the ingredients that shape personality and the ways in which personality in turn affects the behavior. Several systems for thinking about personality are described. In addition, the domains in which individuals are typically expected to function are reviewed, with particular attention to the ways in which various personality styles affect functioning in each domain. Patterns of behavior that are frequently pathological in nature, such as impulsive, compulsive, and avoidant behaviors, are examined. Finally, approaches to the assessment of behavior and adaptive functioning in the psychiatric interview are reviewed.

Personality Style

An individual’s personality style has a great influence on his or her behavior and adaptive functioning. Personality is shaped from a blend of inborn temperament, genetic strengths and vulnerabilities, and the impact of positive and negative life experiences. Psychiatry is moving toward an improved understanding of human behavior that focuses on the ways that these factors interact with one another.

There is evidence of striking variation among neonates in their capacity to tolerate frustration, which reflects their inborn temperaments (Thomas et al. 1963). Such individual differences in temperament form the biological substrate that interacts with early development. Temperament affects the degree to which different infants are susceptible to distress as well as their variations in attachment style (Rothbart and Ahadi 1994). Mr. A’s high tolerance for frustration was an advantage as an infant; his mother considered him an easy baby who was not too demanding. In contrast, only when Mr. B’s repeated bouts of colic in his first year of life ended could he assume the role of family prankster.

Clinical Vignette 1

Mr. A, a successful 48-year-old attorney, is married and has three children. He has enjoyed the position of partner in his large corporate law firm for many years, yet he continues to work long hours. He often wishes he had enough time and energy to really enjoy his children, but he does manage to spend weekends with his family at their country home. He feels satisfied with his work and particularly enjoys his days in court, where he is known as a polished orator and a tough opponent who is likely to make clever legal arguments. His wife sometimes complains that he is too dedicated to work and too worried about money to enjoy the rewards of his labor. She wishes he would let loose and have fun more often, but she is generally satisfied with their marriage.

As a baby, Mr. A was considered easy, seldom ruffled by the inevitable delays of gratification in being fed and changed. He was a bright and cheerful child until age 10 years, when his father was killed in a car accident while driving home from work. After his father’s death, his mother noticed that he became serious and sad, responding to the loss by becoming the “little man” of the family and by always watching out for his little brother, 3 years younger. His mother was particularly worried about this because her sister had a history of severe depression. In high school, he was class president and an excellent track-and-field athlete. No one was surprised when he studied in government college and entered law school.
Genetic factors of various types also play a role in development, particularly when they interact with environmental factors. Mr. A’s mother was correct to be concerned that both his father’s death when Mr. A was young and her sister’s history of depression placed him at higher risk. Brown and Harris (1989) have demonstrated a clear link between early loss of a parent and vulnerability to depression in the face of later stressful life events. Extending these findings, Kendler et al. (2002) demonstrated increased risk for major depression in subjects with parental death and parental separation and in alcohol dependence after parental separation but not parental death. Interestingly, the impact of parental death on rates of depression was less long-lasting than was the impact of parental separation.

Inherited characteristics can also be protective; because Mr. A is intelligent, he was able to become a talented lawyer. In contrast, Mr. B has no family history of mental illness. His hypermasculine style is reminiscent of his father’s and is influenced both by genetics and by his relationship with his father. While genetic factors are thought to account for between 30 and 60% of the variance in adult personality traits (Carey and DiLalla 1994), more recent studies increasingly suggest that shared and nonshared environmental factors rather than genetics may play a substantial role in accounting for the observed quality of infant–caregiver interactions (Roisman and Fraley 2006).

Life experiences also have an impact on an individual and affect her or his behavior for better or worse. After his father’s death, Mr. A developed responsibility and conscientiousness atypical of a 10-year-old in addition to incurring a greater risk of depression. In contrast to the death of Mr. A’s father, which was beyond his control, Mr. B’s knee injury was probably the result of his own actions. His injury ended his dream of playing professional football but helped point him in the direction of a successful business career. Considering whether particular experiences are the result of fate in contrast to whether they are partially brought about by the person’s own actions can be important in thinking about their impact and meaning.

While psychiatrists have long suspected links between early life experiences, especially traumatic ones, and adult psychopathology, these connections are just now being clearly, empirically demonstrated. For example, in one recent study, childhood verbal abuse conferred an increased likelihood of borderline, narcissistic, paranoid, schizoid, and schizotypal personality disorder during adolescence that was independent of other facts like temperament, physical and sexual abuse, use of corporal punishment, parental psychopathology, and co-occurring psychiatric disorders (Johnson et al. 2001). Further, as the relationships between genetic propensities expressed as temperament or personality factors and environmental influences have been explicated, some fascinating interactions have emerged. For example, one recent study suggested that high levels of the personality trait of sensation seeking, which appears to be genetically mediated, might result in a high incidence of adverse life events that would in turn help to precipitate depression (Farmer et al. 2001). More recently, research suggests that genetic factors may moderate the risk of depression in response to stressful life events. For example, the depressogenic effects of stressful life events was significantly greater in groups of women with two short alleles on their serotonin transporter gene than for those with one or no short allele. This functional polymorphism in the serotonin transporter gene was demonstrated to moderate the association between stressful life events and depression by affecting the processing of negative emotion in those with two short alleles (Jacobs et al. 2006). In practice, the reciprocal interactions of the intrapsychic experiences of a person, his or her genetics, and current and past environmental influences make the evaluation of how these factors interact difficult. Oldham (2005) note that a fair amount of the reason we behave as we do relates to “hardwiring,” such as temperament, which is clearly heritable. But beginning in earliest life, the influence of the family caretakers and environmental experiences begin to create a bidirectional process. For example, a placid temperament in an infant elicits reactions in parents and caretakers, which in turn affects the development of personality style. This process continues throughout childhood and adult life. For example, Mr. A’s affective state after the loss of his father probably colored his behavior in the world as

Clinical Vignette 2

Mr. B is a 35-year-old divorced advertising executive. He enjoys his powerful role within his company and is well known for his impressively slick presentations. However, one problem for Mr. B in his career has been his difficulty in keeping personal and work lives separate; during his fling with a junior colleague, his coworkers noted that he was more concerned with flirting than with finishing an important project. He seems to delight in the macho image he projects, basking in the attention of women at work and annoying other men with his tales of previous romantic conquests. These behaviors have kept Mr. B from being promoted to an even more prominent position. Mr. B’s family suspects that he will never have a successful marriage until he stops being a “ladies’ man.”

As a baby, Mr. B was fussy and difficult owing to repeated bouts of colic in the first year of life. Once he recovered, however, he rapidly became the family entertainer. The youngest of five children, he was known for his antics and pranks. When he entered adolescence, Mr. B became engrossed in bodybuilding and football, quickly learning that his athletic prowess made him the heartthrob of his high school class. Mr. B’s father had also been a star athlete and responded to his athletic interests by coaching and encouraging him.

Although Mr. B was intelligent and graduated near the top of his high school class, he was far more interested in organizing parties. College was initially rough for Mr. B, who by then had become accustomed to being on top at high school. In college, he changed his major several times, trying to figure out what image he was trying to build for himself. His fantasies of becoming a National Football League defensive back were dashed by a knee injury during his junior year, which was largely the result of his overtraining and insistence on pushing himself to his limits. After this, Mr. B devoted himself to learning all about the business world instead. Networking and social chatter came naturally to Mr. B, allowing him to rise rapidly within the advertising world. In fact, he proposed to his wife soon after they met at a business cocktail party; she was his boss’ date for the evening. The marriage ended less than 2 years later when she discovered the affair with his coworker.
well as his experience of relationships and events in daily life. Separating aspects of functioning related to his affective state from external reality would be a problem and probably impossible.

Thinking about personality, style and behavior go hand in hand; as Oldham (2005) have pointed out, “in many important ways we are what we do. The ‘what’ of personality is easier to come by than the ‘why’ and each of us has a personality style that is unique, almost like a fingerprint. At a school reunion, recognition of classmates not seen for decades derives as much from familiar behavior as from physical appearance.”

Personality styles have been described in a variety of ways with use of different models of normal personality variation. These models are either categorical or dimensional in nature. In a categorical model, a person is described as meeting or not meeting the criteria for various diagnostic categories. In a dimensional model of personality, a person is evaluated in terms of the blend of various traits or factors he or she possesses, measured on a continuum. In general, as a person moves toward the extreme end of a given continuum in the dimensional model, she or he becomes more likely to meet the criteria for a categorical diagnosis. Some dimensional models set a threshold beyond which a given characteristic is likely to be a problem or pathological.

The categorical model is a more common approach to diagnosis within clinical psychiatry and within medicine in general. However, if Mr. A does not have obsessive–compulsive personality disorder, the unique characteristics of his personality style will not be captured within a categorical model. In addition, the categorical model suggests that the categories in which diagnoses are given are not overlapping. In contrast, a dimensional model allows the retention of important information about a person’s blend of traits but says less about how pathological these patterns are, and is more difficult to use clinically than a straightforward categorical diagnosis. It now seems clear that useful information is gained from both categorical and dimensional approaches to examining personality. At present, the conceptualization of personality disorders within the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) “represents the categorical perspective that personality disorders are qualitatively distinct syndromes” but it is acknowledged that “an alternative to the categorical approach is the dimensional perspective that personality disorders represent maladaptive variants of personality traits that merge imperceptibly into normality and into one another” (American Psychiatric Association 2000). Oldham and Skodol (2000), among others, urged that elements of both categorical and dimensional systems be included when revisions are made in DSM-V, and a joint committee of the American Psychiatric Association and the National Institute of Mental Health concluded that there was a clear need for dimensional models to be developed and for their usefulness to be compared with existing typologies (Widiger and Mullins-Sweatt 2005).

It is likely that certain ways of looking at personality are more useful for a particular purpose than others. For example, an examination of three-dimensional representations of DSM-IV-TR personality disorders and standard categories. In an empirical study of 668 patients comparing personality disorder categories, dimensional representations of those categories based on criteria counts and three- and five-factor personality dimensions with respect to their associations with psychosocial functioning, DSM-IV-TR dimensions best predicted functional impairment (Skodol et al. 2005). However, it may be that the three- or five-factor model would better predict treatment response or development of a therapeutic alliance in treatment, for example.

Taking an even longer view, Depue and Lensenweger (2006) have suggested that the ultimate goal would be the development of a neurobehavioral dimensional model of personality in which personality disturbance is seen “as the product of a matrix of highly interactive systems of neurobehavioral processes” that “interacts with the environment through time and across context, including developmental transitions, to allow for the emergence of personality pathology.” Others have proposed a prototype-matching approach to diagnosing personality disorders in which models of various personality styles are constructed and psychiatrists make diagnosis by matching their patient to the best available prototype (Westen and Shedler 2000). A large new collaborative longitudinal study of personality disorders is currently underway and will provide empirical evidence as to the utility of various approaches to studying personality over time, as well as yielding important information about the course of personality disorders measured in a variety of ways (Gunderson et al. 2000).

In current DSM-IV-TR terms, Mr. A does not meet the full criteria for any of the 10 personality disorders even though he shows some features of obsessive–compulsive personality disorder. He is excessively devoted to work to the exclusion of leisure and has a tendency to be overly cautious with money. In contrast, Mr. B would receive a diagnosis of histrionic personality disorder because he is often sexually seductive, is uncomfortable when he is not the center of attention, and consistently uses his physical appearance to draw attention to himself. He is emotionally shallow and tends to portray himself as a “hip” advertising executive. Although others may not see their relationships with him as intimate, Mr. B tends to assume that his relationships are more intimate than they actually are. However, a diagnosis of histrionic personality disorder would still mean overlooking the several aspects of Mr. B’s personality that are narcissistic in nature but do not meet full criteria for narcissistic personality disorder (Farmer et al. 2001).

Oldham and Morris (1995) translated each of the personality disorders of the DSM-IV-TR system into a less pathological collection of categories that describe normal personality styles. In their system, a cross between a categorical and a dimensional model, conscientiousness is the positive personality trait that in excess becomes obsessive–compulsive personality disorder. In Mr. A’s case, both the positive aspects of his conscientiousness in helping him to achieve his goals at work and the negative impact of this trait on his wife and children when he works too hard are evident. In this model, being dramatic is a character style that when overdone becomes histrionic; self-confidence in excess becomes narcissism. A literature review by Widiger and Costa (1994) supports the hypothesis that DSM-IV-TR personality disorders represent extreme variants of normal personality traits. Table 38–1 summarizes the personality style–personality disorder continuum described by Oldham and Morris.

A continuum model such as this one acknowledges that whereas too much of a good thing may constitute
a disorder, everyone’s personality consists of traits that can be adaptive or maladaptive. The quantity rather than the quality of a given trait is often what makes it a problem or adaptive. Similarly, flexibility and variability are important determinants of a person’s adaptive capacity.

Examples of dimensional models of personality include the five-factor model (Widiger et al. 1994, Widiger 2000, Stone 2002), Cloninger’s seven-factor model (Cloninger 1987, Cloninger et al. 1993, Gillespie and Cloninger 2003), and the biogenic spectrum model of Siever and Davis (1991). The five-factor model of personality was first suggested by McDougall (1932), and was elaborated and updated by Digman (1990) and McCrae and Costa (1987) among others. In the five-factor model, personality traits are described in terms of a taxonomy of five dimensions. These include neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. Someone with an obsessive–compulsive personality style, such as Mr. A, is likely to score high on the factor of conscientiousness in the obsessive–compulsive personality style. People with obsessive styles or personality disorders typically score high in terms of neuroticism, anxiety, hostility, depression, and self-consciousness. Those with obsessive styles or personality disorders typically score low on factors such as extraversion, openness, and agreeableness. In contrast, Mr. B scores high on traits such as gregariousness and excitement seeking (extraversion) as well as fantasy and artistic sensibility (openness). However, he has particular difficulty in being appropriately conscientious. As Stone (2002) has noted, examining Mr. A and Mr. B in this dimensional way allows greater diagnostic subtlety because it allows clinicians to set down all of the relevant strong and weak points of an individual’s character as well as to evaluate that these facets may facilitate (such as conscientiousness) or impede (such as low openness) treatment.

Table 38–2 summarizes the factors of the five-factor model and their relationship to DSM-IV-TR categories.

A second dimensional model of personality is Cloninger’s seven-factor model of temperament and character (Cloninger 1987, Cloninger et al. 1993) (Table 38–3). In this model, a patient’s behavior is evaluated on seven separate dimensions. Four of the seven dimensions are related to temperament and have been shown to be independently heritable, manifested early in life, and involved in early perceptual memory and habit formation. These four dimensions include novelty seeking, harm avoidance, reward dependence, and persistence. Mr. A is particularly attuned to avoiding harm, and his behavior is typically characterized by a high degree of persistence; he is cautious and thoughtful in approaching new situations and doggedly pursues his goals. Mr. B ranks high on Cloninger’s dimensions of novelty seeking and reward dependence; he is quickly bored by things that are not new and exciting and actively seeks the approval and attention of others. Figure 38–1 is a schematic representation of Cloninger’s model.

Cloninger also describes three dimensions of character, namely, self-directedness, cooperativeness, and self-transcendence. The blend of these three characteristics that an individual possesses helps to determine self-concept, such

as whether the individual identifies himself or herself as an autonomous individual, as an integral part of humanity, and as a part of the universe as a whole. Those with low degrees of self-directedness and low degrees of cooperativeness are more likely to have personality disorders (Svrakic et al. 1993). Someone as relatively well adapted as Mr. A is likely to rate high on the traits of self-directedness, cooperativeness, and self-transcendence. In contrast, Mr. B may be less self-directed and less cooperative than Mr. A.

A third dimensional model of personality is the biogenic spectrum model of Siever and Davis (Siever and Davus 1991, Coccaro and Siever 2005). This model proposes that certain personality styles and disorders are associated with and are characterological variants of various Axis I disorders. Thus, personality disorders are not extreme variants of normal but are characterological variants of Axis I disorders. For example, Mr. A’s obsessive-compulsive style may be a variant of anxiety disorder; Mr. B’s histrionic personality disorder may be a variant of an impulse control disorder. The biogenic spectrum model may be useful in guiding treatment, such as using anxiolytics to treat avoidant personality disorder because it is considered to be on a spectrum with Axis I anxiety disorders. There is growing evidence that the biogenic spectrum model is useful for at least some Axis I/Axis II disorders. One example is the link between schizophrenia and schizotypal personality disorder in which those with the Axis II disorder demonstrate a better capacity for buffering in certain frontal brain regions as shown by functional imaging as compared with those with the full-blown Axis I disorder (Kirkman and Siever 2000). Table 38–4 presents details of the biogenic model.

Domains of Functioning

Each person’s unique personality style is reflected in the various domains in which the person functions. Domains of functioning in which people are evaluated include social and interpersonal functioning, occupational functioning, and leisure. Within DSM-IV-TR, Axis V, the Global Assessment of Functioning, provides a 100-point scale with which to rate a person’s overall level of adaptation. It provides a useful global rating of adaptive function that assesses the degree of symptoms and the capacity to function in social

Social and Interpersonal Functioning

Interpersonal styles greatly affect social functioning, which in turn has a large impact on both work- and leisure-time functioning. Distinctive individual personality styles affect a person’s perception of the importance of relationships with others as well as the quality and depth of the bonds they can form. Those with solitary traits are unlikely to crave and seek close relationships, whereas those with a devoted style become uneasy and feel incomplete if they are not with others. Vigilant people are cautious of the attentions of others, whereas dramatic types thrive on the admiration of their peers. Those who are mercurial often run “hot” and “cold” in their relationships with others, sometimes expressing their feelings in ways that offend others; sensitive types are easily affected by the perspectives and behavior of others but tend to keep their feelings to themselves.

The Social Adjustment Scale (Weissman et al. 1974, 2001) provides a quantitative way to investigate several types of interpersonal functioning (Table 38–5) including a person’s relationships with family of origin, spouse or partner, children, work colleagues, and friends and acquaintances. Some questions assess the degree of overt fighting and friction that is present in these relationships and whether it causes the person to minimize or avoid contact with others.

</table>

*Each domain is scored on a 5-point scale ranging from 1 (not a problem) to 5 (an extreme problem). In addition, a global score in each domain is assigned by the use of the same scale.

The degree to which a person feels reticent about being reasonably open within each relationship and the degree to which others are depended on to provide various forms of help, such as advice and financial support, are also important indicators of the quality of interpersonal connections. In addition, the scale provides a way to assess whether someone initiates contact with others, whether the individual feels an urge to be defiant or rebellious, and whether the individual feels overly concerned, guilty, or resentful within each relationship. Inherent in these assessments of functioning is an assumption that to be successful, relationships should be interpersonally relatively free of friction and arguments, reciprocal, and supportive. In addition, each person’s experience of the relationship should be comfortable and relatively conflict free.

Benjamin’s Structural Analysis of Social Behavior (Figure 38–2) provides another means of assessing recurrent patterns in a person’s interactions with others (Benjamin 1986b). It has three dimensions: (1) the focus of the interaction, (2) affiliation–hostility, the tone of the interaction (loving versus hating), and (3) interdependence–independence, which can address the dimensions of enmeshment vs. differentiation. The focus in the Structural Analysis...
of Social Behavior can be on another person, on oneself in relation to another person, or on inward, internal aspects of the self. As an example, a woman cleans house and runs errands with her family in mind; the focus is on others, and the tone of the action is friendly. The act of running the household suggests that the woman influences others in the family, so the score on the third dimension is in the controlling-interdependent direction. The Structural Analysis of Social Behavior is widely used in research settings as an assessment tool to describe and quantify a person’s mode of interpersonal functioning in various relationships (Benjamin et al. 2006).

**Occupational Functioning**

Assessing adaptive occupational functioning requires examining the ways in which an individual completes tasks, takes and gives orders, delegates responsibilities, and cooperates with others. Job situations also require an ability to balance demands, obey regulations, and make decisions. Clearly, success in these tasks in part depends on one’s capacity for interpersonal functioning. A patient who is mercurial in personal relationships is also likely to have difficulty with coworkers. Work is often the central domain of concern for those with conscientious styles and for those with aggressive styles. For people with these styles of functioning, work is synonymous with fun. In contrast, for those with other personality styles, occupational functioning can be a problem because it is given too little importance. Leisurely people get by with the bare minimum of work, whereas those who are adventurous like challenges but tend to have difficulty with authority at work. Those with a devoted style tend to remain loyal even to jobs they dislike; thus, the problem with work for them is an intrapersonal problem rather than an interpersonal one.

Weissman’s Social Adjustment Scale also provides a means of evaluating a person’s occupational functioning. The scale focuses on both externally observable behaviors, such as number of days lost in a month and the degree of impairment of performance at work, as well as internal states, such as feeling inadequate, angry, and distressed at work. In addition, whether a person is distressed, disinterested, and bored by work is also assessed. These questions begin to suggest what adaptive occupational functioning comprises, namely, that it consists of being engaged and feeling satisfied about and competent at work. In addition, the Social Adjustment Scale quantifies aspects of leisure, such as the frequency with which such activities are pursued. It can be helpful in assessing whether a patient’s leisure-time contacts with others are diminished. The Social Adjustment Scale quantifies aspects of leisure, such as how many social events one has attended in the last month. The experience of loneliness or boredom during free time as well as the person’s ability to compensate for these painful states yields a measure of leisure-time adaptation.

**Assessing Behavior and Adaptive Functioning in the Clinical Interview**

Finding out about a patient’s personality style, level of adaptive functioning, and usual patterns of behavior is one of the major tasks of the psychiatric interview. A psychiatrist gains important information from what a patient and those people close to the patient say about her or his behavior. However, a psychiatrist also gains invaluable information by closely observing the person during the interview itself. Whether the psychiatrist is quickly sizing up an agitated patient during a psychiatric emergency or carefully noticing how a patient shifts in the chair during a psychotherapy session, the ability to observe a patient’s behavior is one of a psychiatrist’s most important tools. A patient’s appearance, attitude, and motor behaviors during an interaction with the psychiatrist provide important clues to personality, capacity for interpersonal interactions, and potentially problematic behavior patterns.

**Appearance**

Observing a patient’s appearance includes making a judgment about the overall physical impression of the person reflected by grooming, clothing, poise, and posture. The ability to appear well kempt is impaired in many psychiatric disorders, ranging from the psychotic patient who appears disheveled after being up for several nights to the depressed patient who is disheveled after being up for several nights. A patient who is mercurial in personal relationships is also likely to have difficulty with coworkers. Work is often the central domain of concern for those with conscientious styles and for those with aggressive styles. For people with these styles of functioning, work is synonymous with fun. In contrast, for those with other personality styles, occupational functioning can be a problem because it is given too little importance. Leisurely people get by with the bare minimum of work, whereas those who are adventurous like challenges but tend to have difficulty with authority at work. Those with a devoted style tend to remain loyal even to jobs they dislike; thus, the problem with work for them is an intrapersonal problem rather than an interpersonal one.

**Clinical Vignette 3**

Mr. C, a young schizophrenic man, attempted to avoid hospitalization by beginning to shave more regularly and cutting his fingernails. However, he remained unwilling and unable to have his hair cut, attempting to disguise its length by wearing it up under a baseball cap when going outside.

**Clinical Vignette 4**

Ms. D, a middle-aged woman, came to the emergency department claiming that she had run out of Valium and that her prescribing physician was out of town. Her story was convincing and the resident physician was about to give her a prescription when he noted on close examination that she had a dirty hem on both her pants and her jacket sleeves, which seemed inconsistent with her presentation of herself as an executive secretary. After pressing her for more details of her story and consulting with another emergency department, he determined that the patient was actually a homeless woman who got prescriptions from hospitals and then sold them on the street.
patient dressed in dark, somber tones, and slumped in the chair. Clothing often reveals aspects of personality; patients with extroverted, hysterical, or dramatic personalities often wear brightly colored, unusual clothes and are often garrulously made up. Problems with appearance can suggest the possibility of other functional impairments as well.

The motivation and degree of volitional control over appearance must usually be inferred; the character of Klinger in the television series *M*A*S*H* appeared dressed in female clothing in an attempt to earn a discharge from the Army. On the other hand, a patient may try to disguise a psychiatric disorder by focusing on making her or his appearance as normal as possible.

At times, appearance may provide an important clue of an inconsistency in a patient’s verbal presentation and suggest a serious behavior problem.

**Attitude and Cooperation**

The interviewer can also detect a patient’s attitude and willingness to cooperate during an examination. Attitude and cooperation are related but not identical concepts; a paranoid patient may have a suspicious attitude but may cooperate by answering the interviewer’s questions nonetheless. Often, however, a person’s attitude and ability to cooperate are both affected by psychiatric illness. Patients may be friendly or hostile, seductive, defensive, or apathetic. During the psychiatric interview, they may seem attentive or disinterested and be frank or evasive and guarded. Again, each of these attitudes and the degree of cooperation a patient exhibits can depend on the underlying psychiatric state or can reflect a conscious manipulation on the part of the patient for the sake of achieving a desired goal. Attitude and degree of cooperativeness with an interviewer yield data about a patient’s capacity to establish rapport and relate to others, thereby suggesting the person’s general level of interpersonal functioning.

**Motor Behavior**

The astute examiner can also observe motor behaviors that provide clues to a patient’s internal state. First, the overall level of activity should be noted. Behavioral activity is often quantitatively increased in patients with mania or anxiety disorders, whereas it may be decreased in those with depression or intoxication. In addition, impulsivity can sometimes be revealed by motor behaviors, as when a person pounds on a wall or hurls an object. Motor behavior can also provide clues to personality; the dramatic patient often gesticulates freely during conversation, whereas the obsessive patient often conveys a sense of constricted facial movements and gestures. The types of behaviors associated with overactivity may include restlessness, pacing, hand-wringing, or other forms of agitation. In contrast, psychomotor retardation is a slowing of the usual body movements. A depressed patient with psychomotor slowing may be observed sitting perfectly still, staring into space. Similarly, patients with underlying neurological disorders such as Parkinson’s disease or those who are taking medicines that produce parkinsonism may exhibit motor slowing in the form of lack of facial expressiveness and loss of the body movements and gestures that often accompany speech.

Other types of motor behaviors may be unusual or qualitatively different from those observed in normal people.

Tics are sudden, rapid, involuntary stereotyped movements, or vocalizations. Examples of simple tics include facial grimaces, blinking, and neck jerking or shrugging as well as throat clearing, coughing, barking, or snorting vocal sounds. More complex motor tics include jumping, touching, or grooming behaviors as well as vocalizations consisting of complex phrases, socially unacceptable obscene words (coprolalia), or repeating of one’s own words or the words of others (palilalia and echolalia, respectively). These tics are exacerbated by stress and anxiety and can be voluntarily suppressed for a time, although they are ultimately experienced as irresistible. They are generally believed to disappear during sleep.

Another clinically relevant way of approaching the task of assessing a patient’s behavior was suggested by Hal-leck (1994). He suggested that in addition to focusing on appearance, attitude, and cooperation in the clinical evaluation, the interviewer can assess (1) the patient’s physical and emotional attractiveness; (2) his or her means of seeking control and whether control is a central issue; and (3) the degree to which the patient is dependent, passive, aggressive, attention seeking, private, or exploitative in his or her behaviors. Although patients with different styles have different motives for and various ways of expressing these types of behaviors, examining their behavior in each of these categories is likely to provide a productive additional approach to evaluating behavior and adaptive functioning.

**Problematic Patterns of Behavior**

Problematic patterns of behavior, such as impulsivity, compulsion, and avoidance, cut across diagnostic groups; looking for these patterns can be a fruitful way of characterizing the aspects of maladaptive functioning. Each of these three patterns can arise from a wide array of psychiatric problems. For example, intoxicated people are often disinhibited and impulsive, acting in ways that they would not act if they were sober. However, a manic patient may also be impulsive, often spending money freely or engaging in sexual activity without considering the consequences of these actions. Labeling each of these patterns of behavior impulsive is an important first step in reaching a diagnosis. In addition, finding one type of impulsive behavior should prompt the psychiatrist to look for others and to predict that the patient may act impulsively in the future.

**Impulsive Behaviors**

Impulsive behaviors are actions that arise without much delay between the formation of an idea or desire and its gratification in action. Not all impulsive behavior is pathological; in a muted and well-modulated form, impulsivity is closer to spontaneity, as Mr. E’s necklace purchase suggests. Certain personality styles, such as dramatic characters, are
Impulsive, Compulsive, and Avoidant Patterns

Ms. F, 23 years old, is undergoing evaluation in the emergency department after a suicide attempt by acetaminophen overdose. She reports that the attempt followed a fight with her boyfriend, after which she locked herself in the bathroom and swallowed several handfuls of pills before he broke the lock on the door and called for help. In the emergency department, Ms. F is tearful and angry because she attempted to strike his head and chest with her fists when he was initially allowed to see her. Her psychiatric history is notable for two past suicide attempts and problem weekend bouts of drinking accompanied by blackouts.

However, in its more extreme forms, impulsivity is often pathological, as the case of Ms. F shows. A number of behaviors that seem dissimilar may have impulsivity as the common and uniting thread. In DSM-IV-TR terms, Ms. F’s history suggests a panoply of disorders including major depressive disorder, bulimia nervosa, impulse control disorder not otherwise specified (cigarette burns), alcohol dependence, and a borderline personality disorder (stormy interpersonal relationships and self-injurious behaviors, such as substance abuse, suicide attempts, and self-mutilation). However, all of her problem behaviors may be more parsimoniously described as impulse-ridden than by reference to each DSM-IV-TR diagnosis.

Another advantage of thinking about impulsivity as a distinct pattern of problem behavior is that impulsivity in one sphere is often accompanied by impulsive behaviors in other arenas. Thus, on learning that Ms. F has overdosed on pills, the emergency department psychiatrist should already be wondering about self-mutilation, eating disorders, and substance abuse. Thinking about impulsivity more generally across an array of impulsive behavioral types has already proved useful in eating disorder research. In a study of the relationship between impulsivity and eating disorders, Fahy and Eisler (1993) reported that 51% of 67 bulimic subjects interviewed had at least one other form of impulsive behavior. These subjects also reported more severe eating disturbances and were less quick to respond to treatment with medication than were bulimic subjects without other comorbid forms of impulsivity. Fernández-Arandaa et al. (2006) demonstrated lifetime prevalence rates of 23.8% for other impulse control disorders among women with bulimia nervosa including compulsive buying in 17% and intermittent explosive disorder in 13%. Corstorphine et al. (2007) suggested that any reported childhood trauma, and especially sexual abuse, was associated with a higher number of impulsive behaviors and with the presence of multi-impulsivity in eating disordered patients and was associated with self-cutting and substance abuse. Whiteside and Lynam (2003) suggested that four personality dimensions were differentially related to impulsive behavior including urgency, sensation seeking, (lack of) premeditation, and (lack of) perseverance. Using this model, Claes et al. (2005) demonstrated that patients with bulimia showed consistently more urgency and sensation seeking and less premeditation and perseverance than restrictive anorexia nervosa patients, with the binge–purging anorectic subtype being situated between these two groups.

Behaviors that are frequently impulsive in nature include self-mutilation and suicide, substance abuse, pathological gambling, binging and purging eating behaviors, and hair pulling. In addition, urges to steal (kleptomania), to set fires (pyromania), or to engage in sexually perverse or unusual behaviors (paraphilias) also result in impulsive behaviors (Table 38–6).

Different types of impulsive behaviors are often experienced in similar ways by patients. One hallmark of impulsive acts is that they are often preceded by a growing internal sense of tension and discomfort that is reduced by the impulsive act itself. Whether the act is hair pulling (trichotillomania) that results in baldness or pathological gambling that has severe financial consequences, the person is likely to feel that she or he can no longer tolerate the internal tension and that giving in to the impulse will provide relief to an uncomfortable internal state.

Ms. G, a 21-year-old woman with borderline personality disorder, carved the word “monster” on her arm. Of this act she said, “I was feeling so tense and angry, like there was a tornado inside of me. As I focused on the small red lines I made with the razor, I began to feel better. The physical pain let me center my attention on my body, and my angry feelings seemed to fade away.”

A second characteristic of impulsive acts is that they are often frankly pleasurable at the moment of action even if the person is extremely remorseful afterward.
A third hallmark of impulsive behaviors is that patients are often relatively impervious to the consequences of their actions at the time and tend to underestimate their chances of being caught.

Patients with impulsive patterns of behavior also tend to underestimate the chances of being caught by a spouse or friend.

In addition, the impulsive nature of the action itself may increase the odds of apprehension and punishment.

Another feature common to impulsive behaviors is that they often involve a binge, an episode of engaging in a behavior that seems out of control and cannot be terminated by the patient. Often, the binge ends only when an external constraint forces the patient to abandon the action. An eating binge and the relapse of an alcoholic person are often similarly described: “Once I started eating (drinking) I couldn’t stop. I just kept on stuffing myself (ordering drinks) until I was too exhausted and sick (drunk and broke) to continue.” It is noteworthy that impulsively binging on a substance such as alcohol sets the stage for further impulsive behaviors secondary to intoxication.

Apart from the clinical utility of thinking of various impulsive behaviors in similar terms, there is also evidence of an underlying biological defect that commonly gives rise to a variety of impulsive behaviors. Linnoila et al. (1993) reviewed a number of studies in support of the idea that low cerebrospinal fluid concentration of 5-hydroxyindoleacetic acid, the main by-product of serotonin metabolism, was related to impaired impulse control as well as increased aggressiveness. They cited several types of studies that supported this relationship, including studies demonstrating that (1) patients with unipolar depression who made violent suicide attempts often had low cerebrospinal fluid levels of 5-hydroxyindoleacetic acid, (2) there is a strong negative correlation between lifetime aggressive behaviors and cerebrospinal fluid levels of 5-hydroxyindoleacetic acid, and (3) young abstinent alcoholic men had lower cerebrospinal fluid levels of 5-hydroxyindoleacetic acid than control subjects did. More recently, links between the personality trait of impulsiveness, the behavior of deliberate self-harm, and specific serotonin receptor genotypes have been established (Evans et al. 2000). In addition, evidence that a deletion/insertion polymorphism within the 5-HT transporter promoter gene has been implicated in several psychopathological phenotypes related to disturbed impulse control. Retz et al. (2004) found a significant excess of the short (s) allele and the s/s genotype in patients characterized by recurrent and overt violent behavior in a group of 153 males referred for forensic psychiatric examination.

Compulsive Behaviors

In its muted form, compulsivity can be seen as carefullness or attention to detail. It is easy to see how such attention to detail is helpful in a variety of settings in daily life. Many jobs, such as Ms. L’s, depend on thoroughness and a willingness to keep working until the books are balanced to the last penny. However, compulsive behaviors become a problem when they begin to consume much more time than necessary and when they are a response to nonsensical thoughts (obsessions), as in Mr. M’s case.

At first glance, compulsive patterns seem to be the opposite of impulsive patterns of behavior. In compulsive
Clinical Vignette 13

Mr. M is a 48-year-old executive who suffers from obsessive-compulsive disorder. Despite treatment with a variety of medications including fluoxetine and clomipramine, he has been unable to rid himself of the idea that he has accidentally hit someone while driving to work. Any bump in the road that he notices sets off this obsessive worry, and he feels compelled to circle back to the scene to double-check that he is not guilty of a hit-and-run accident. Sometimes he is not reassured by this initial check and continues to circle the area until “something clicks” and he feels certain that he has not hit anyone. This behavior makes Mr. M as much as 2 hours late for work.

In fact, there is evidence that impulsive and compulsive behaviors tend to co-occur in the same individual. In one study, impulsive aggression was found to be common in patients with obsessive-compulsive disorder (Stein and Hollander 1993). The authors theorized that obsessive-compulsive disorder and impulsivity may both arise from a similar problem in the self-regulation of behavior due to a neuroanatomical lesion in the serotonergic system. They found that treating the obsessive-compulsive disorder with serotonin reuptake inhibitors also decreased these patients’ impulsive aggression, which led Hollander and Rosen (2000) to conceptualize impulse control disorders as a subset of the obsessive-compulsive spectrum with underlying commonalities in serotonergic dysfunction giving rise to both impulsive and compulsive behaviors. In this model, disorders of impulsivity and compulsivity have in common the inability to delay or inhibit repetitive behaviors (Hollander et al. 2005). Empirical evidence supporting the concept of an obsessive-compulsive spectrum in which impulsivity is a subset exists, such as Skitch and Hodgkins’ (2004) study of 262 pathological gamblers who demonstrated significantly elevated scores on measures of both impulsivity and compulsivity.

The compulsions of obsessive-compulsive disorder, food-restricting behaviors such as those found in anorexia nervosa, and compulsive sexual behavior are common types of compulsivity (see Table 38–6). Like impulsive behaviors, compulsions share common features and are experienced in similar ways by patients. However, the driving force behind compulsive behaviors is not the gratification of impulses, but rather the prevention or reduction of anxiety and distress.

The concept that compulsive behavior is an attempt to reduce anxiety is easy to understand when the behavior is a response to an obsessive thought. However, even when the compulsive behavior is sexual in nature, it is driven by the need for anxiety reduction rather than by sexual desire (Coleman 1992).

Clinical Vignette 15

Mr. O is a 38-year-old man who is distressed by the compulsion to masturbate that he feels nearly every morning on awakening with an erection. He describes the activity in detached terms, stating, “I think it’s a waste of time. I don’t enjoy it. I’m often making a mental list of things I have to do at work or even watching morning television programs while I’m masturbating. But I feel nervous for the rest of the day if I don’t do it.”

Avoidant Behaviors

As with impulsivity and compulsivity, avoidance in its modulated form can be positive; learning from past negative experiences and avoiding prior mistakes are important capacities. Mr. P’s avoidance of automated teller machines at night seems a sensible and self-protective decision. In contrast, Ms. Q’s fears about social interactions with others at work are a problem; avoiding social situations also means avoiding a chance for promotion.

Clinical Vignette 16

Mr. P is a 55-year-old man who was robbed at gunpoint 1 year ago after visiting an automated teller machine to withdraw money. Since the robbery, he has felt somewhat afraid when using the automated teller machine in the daytime, although this fear has diminished over time. He has avoided needing to use the automated teller machine at night by carefully planning his finances since the robbery.

Clinical Vignette 17

Ms. Q is a 40-year-old woman who works in a university library. She has gradually become more accustomed to dealing with patrons at the reference desk but continues to prefer the solitary task of looking for books that are misshelved. Despite her boss’s encouragement, she has decided not to apply for a higher level job that would involve teaching groups of new employees about the library computer system. She realizes that she is passing up a good career opportunity, but she also recognizes that the public speaking and writing on the board that this new position would entail are terrifying to her. She worries that she will stammer and blush and make a fool of herself in front of the group. Even now, she feels uncomfortable on her lunch break because she is reluctant to join other employees in the cafeteria.

One prevalent condition that gives rise to avoidant behavior is agoraphobia (see Table 38–6). The agora was a crowded open-air market in ancient Athens. The word agoraphobia...
literally means “fear of the agora” (Stedman’s Medical Dictionary 1982). Modern situations equivalent to the agora include those in which a person is outside of the home alone, in a crowd, standing in line, on a bridge or in a tunnel, or in a bus, train, or car. In each of these situations, help may not be readily available in case of an emergency. Thus, agoraphobia is a condition in which a person has anxiety about being in places or situations from which escape is likely to be embarrassing or difficult. For many people with agoraphobia, the situation they dread is having a panic attack in public. Often what began as a spontaneous attack becomes linked to the situation in which the attack occurred so that the person becomes afraid of that particular place or activity.

Avoidant behaviors usually arise from a patient’s history of being fearful or concerned that he or she will become fearful in a given situation. Because of the past history or the perceived threat, the anxiety-provoking situation is avoided. Avoiding the situation means avoiding the fear and anxiety the situation threatens to produce. For example, Marshall et al. (1992) studied 50 adults in a variety of settings that had the potential to induce phobic avoidance of heights. They found that catastrophic thinking (i.e., imagining various ways of falling) was especially common among those who were afraid of heights and that it was closely correlated with avoidance of height situations. Children with school phobias often avoid school by feigning illness. They are likely to become terrified when school attendance is enforced by their parents, clinging to the parent and crying to avoid being left at school alone.

In a prospective study of over 2000 adolescents, sensitivity to anxiety as assessed by the Anxiety Sensitivity Index among other measures predicted behavioral avoidance, supporting the idea that anxiety sensitivity is a precursor to avoidance behavior. In this study, anxiety sensitivity predicted avoidant behavior regardless of whether or not acute panic had been experienced, suggesting that those who fear autonomic arousal even in the absence of the experience of actual autonomic arousal are more likely to avoid situations that threaten to generate that sensation (Wilson and Hayward 2006).

Another feature common to avoidant behaviors is that they become self-reinforcing and tend to worsen in severity over time if left untreated. This is due to the fact that what Gorman et al. have termed “the fear network” is an evolutionarily conserved brain circuit comprising amygdala, hippocampus, and prefrontal cortex whose job is self-preservation. Given this central role in survival, the fear network tends to react robustly in those with a predisposition to anxiety disorders and to be difficult to quell once stimulated.

A further common feature of avoidant behaviors is their tendency to heighten anticipatory anxiety and precipitate the very reactions that a person is afraid of.

Conclusion
In evaluating the adaptiveness of a person’s behavior, an understanding of the strengths and weaknesses of various character styles and the constraints and demands of the external environment is essential. Behavior is the final common pathway for the expression of genetics, temperament, personality traits, and psychiatric symptoms. Behavior is an observable entity in a field where many important aspects of a patient’s internal life must be inferred by the psychiatrist. Although some behaviors are clearly more adaptive than others, emphasizing the strengths of a person’s capacities is important. Even pathological behaviors often represent a person’s best attempt at adaptation; a paranoid patient who installs extra locks on the door may be doing the best she or he can in the face of illness to survive, to cope, and to adapt to the environment the patient perceives around her or him.

Introduction

In the 1990s, many authors began proposing a multilevel analysis for understanding psychopathological phenomena. This fact might indicate a paradigm change for the explanation of human behavior, both normal and pathological. Examining the integration and interaction of biopsychosocial variables in order to explain psychopathological behavior requires simultaneous attention to biological processes, psychological experiences, and the sociocultural context of those persons who suffer from them. However, many authors claim that the tendency to look for biological and psychological explanations for psychiatric disorders has led researchers to underemphasize the importance of sociocultural factors in psychopathological manifestations (Agbayani-Siewert et al. 1999, Aneshensel and Phelan 1999, Fabrega 1993).

From the outset, psychopathological research has usually assumed that mental disorders exist as “objective” states and can be evaluated with universal and standardized criteria, forgetting, in part, the impact of social, economic, cultural, and political factors in the explanation of psychopathological disorders. This oversight is all the more critical when comparing culturally distinct groups. However, in the last 30 years, this oversight has been mitigated by significant contributions in cross-cultural research whose objective has been to understand the cultural component of psychopathology.

This research, which has increased dramatically since the 1970s and 1980s, was consolidated via the creation of a group working on cross-cultural studies for the preparation of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 1994, Mezzich et al. 1993). The Manual contains three kinds of information relating to cultural factors: (a) in the clinical presentation of disorders, a discussion of cultural variants of each disorder, called symptoms dependent on culture and gender; (b) guidelines for a “cultural formulation” of the clinical presentation to help clinicians perform a culturally sensitive diagnosis; and (c) a description of “culture-bound” syndromes, including the name of the disorder, the cultures in which it has been diagnosed, and a brief description of the psychopathology associated with each clinical presentation (the last two sections are included in Appendix I of the DSM-IV-TR). The International Classification of Diseases and Related Health Problems, Tenth Revision (ICD-10) has also been revised and updated to account for cultural factors, as evidenced by the emergence of new diagnostic systems such as the Chinese Classification of Mental Disorders and the Latin American Guide for Psychiatric Diagnosis (Berganza et al. 2001, Mezzich et al. 2001, Mezzich and Salloum 2007). While both of these culturally sensitive diagnostic manuals recognize the value of local cultural requirements to enhance the validity of psychiatric diagnosis, they also illustrate the complementary need to integrate such systems of diagnosis into a global and reliable diagnostic language (Lee 1993, Berganza et al. 2001).

In spite of the advantages suggested by the publication of DSM-IV-TR and other diagnostic systems for the consideration of cultural factors, critical voices continue to call into question how the DSM-IV-TR treats the subject of culture. For example, Brown et al. (1999) claim that researchers have not paid sufficient attention to the ways race, ethnicity, and culture relate to one another and to psychopathology. Despite the apparent conflict between recognizing national and cultural traditions in psychiatric diagnosis and practice on the one hand and, on the other, the drive to find a common diagnostic language that can be applied universally across cultural boundaries, the importance of integrating these two perspectives continues to be discussed (Fabrega 2001).

The existence of a rich modern tradition of cross-cultural research and debate led directly to the increased...
Sociocultural Factors Related to Substance Use Disorders

In turn, the publication of the manual stimulated continued research on the influence of cultural factors on the etiology, symptomatology, course, and treatment outcome of psychopathological disorders. In this chapter, we will focus on cultural considerations pertinent to the use of diagnostic criteria in ethnically and culturally diverse populations. We will also comment briefly on related culture-bound syndromes.

Specific Cultural Considerations

Cognitive Disorders

Less attention has been paid to cultural variants of the cognitive disorders than to other psychopathological forms, probably because of the widespread assumption that this group of disorders is influenced exclusively by biological factors. Nevertheless, these disorders show several kinds of social, cultural, and ethnic influences. Given the etiologically based subtyping of the cognitive disorders, these influences are exerted, first, by effects on the nature and rates of the diseases that are the causative agents of these disorders (Lin and Fabrega 1997).

Socioeconomic factors influence the prevalence rates of diseases affecting the brain. Low industrialization of a country or the poverty of a particular social group tends to increase the rates of infectious diseases, nutritional disorders, toxic exposures (e.g., lead), head injuries, endocrinological abnormalities, and seizure disorders among others (Cruickshank and Beevers 1989). This, in turn, may result in differences in the rates of the subtypes of dementia, of delirium, and of other specific cognitive syndromes (Spector 1979, Westermeyer and Canino 1997).

Cultural factors, such as prohibitions against substance use and variations in sexual mores, also affect the rates of alcohol- and drug-related syndromes as well as of acquired immunodeficiency syndrome (AIDS)-related organic mental disorders (Agarwal and Goeede 1990, Kaslow and Francis 1989). Ethnic determinants are also important. Hypertension and strokes have been suggested to be more prevalent among the African-Americans and some Asian groups; this may result in different rates of multi-infarct dementia (de la Monte et al. 1989). In addition, research on Alzheimer’s dementia is currently evaluating reports of lower rates among the Chinese and the Chinese-Americans as well as the African-Americans (de la Monte et al. 1989, Zhang et al. 1990). The detection and assessment of the cognitive disorders are also influenced by social and cultural factors. Social groups that tolerate and even expect substantial decreases in decision-making and self-care among older persons may not be regarded as pathological milder degrees of disorientation among the elderly (Ikels 1991). Educational-level and cultural differences appear to exert separate but intermingled effects on the inappropriately high identification of cognitive impairment with the Mini-Mental State Examination (MMSE) among several ethnic groups, including the Hispanic, Taiwanese, Chinese, Southeast Asian (Williams 1987), and Afro-Caribbean populations (Richards et al. 2000). Based on a review of the literature and consultations with members of the aboriginal community, Cattarinich et al. (2001) note that differing degrees of acculturation within and between aboriginal groups create problems for cognitive evaluations. On the basis of these and other findings, some researchers have begun to question the adequacy of the MMSE and other cognitive assessment instruments, and as a consequence some practitioners have begun modifying their methods.

Substance Use Disorders

Sociocultural factors exert considerable influence over some aspects of substance use disorders and not others. The prevalence rates of alcohol and drug abuse and dependence vary significantly across different cultures. Lifetime rates for alcoholism, for example, range from 23% among the American Indians to 0.45% among the population of Shanghai (Helzer and Canino 1992). Specific local factors that affect degree of risk for substance-related disorders include patterns of use, attitudes toward substance consumption, accessibility of the drug, physiological reactions to the same drug, and family norms and patterns (Westermeyer and Canino 1997) (Table 39–1). Recent studies of teenagers find that different ethnic groups in the US experience different rates of substance abuse (Turner and Gill 2002). Of even greater concern is the epidemiological finding that rates of alcohol and other substance abuse are higher among the US-born Mexican-Americans than among Mexico-born migrants, and increase with length of stay in the US, indicating either a pathogenic impact of the US residence, a loss of protective social factors with migration, or both. These findings suggest that interventions should be tailored to the needs of different minority and immigrant populations, particularly as substance abuse has been related to other psychological disorders (Vega et al. 1998, Lee 2001, Griffin et al. 2000). In part, these differences may be influenced by the way the local culture influences the definition of pathological substance use through differences in the perception of the impairment caused by high consumption and frequent intoxication (Osterberg 1986). Particular cultural views toward drinking in children, the value of moderation, the tolerance for intoxication, and the association of drinking with family activities and special social occasions appear to influence the degree of risk for alcoholism (Valliant 1986). The availability of a substance also increases its rates of abuse and dependence (Helzer and Canino 1992). Sociocultural factors such as religious proscriptions may exert their influence in this fashion. Heath (2001) has remarked on the long tradition of drug inhalation, from tobacco to hallucinogens, in tropical South America, which contradicts the perception in North America of drug inhalation as a novel, and therefore aberrant, trend (Kirmayer and Groleau 2001).

Several aspects of substance use disorders appear to be less affected by cultural factors. Such aspects include the comorbidity patterns, the nature of dependence syndromes, the age at onset, and the results of laboratory tests and physical examinations (Westermeyer 1989). For example, alcoholism is associated in many societies with abuse of other substances, mania, and antisocial personality as well as with depression and anxiety (Anthony and Helzer 1991). Alcoholism and drug abuse are reliably more common among men, although the sex ratio can vary from 2:1 to 4:1 (Helzer and Canino 1992, Robins et al. 1981). Drug abuse is also more prevalent among urban populations, the less educated, and the young (Anthony and Helzer 1991). The physical symptoms as well as the temporal relationship between onset of use and dependence are substance-specific and also fairly similar across cultures (Berger and Westermeyer 1977).

Schizophrenia and Related Psychotic Disorders

The cross-cultural presentation and course of schizophrenia are among the best-studied aspects of cultural psychiatry. Research has revealed both cross-cultural similarities and differences, both of which are important for elucidating the biological and environmental bases of the disease. A “spectrum” of schizophrenic syndromes—consisting of a combination of certain positive and negative psychotic symptoms—has been found nearly everywhere, although the specific content of hallucinations and delusions as well as the prevalence of visual and other nonauditory hallucinations varies (Krassoevitch et al. 1982, Ndetei and Vadher 1984). Significant cross-cultural variation has been found, however, in several features of the syndrome. Its distribution is not uniform, ranging from 1 in a 1,000 in the non-Western societies to more than 1% in the West; its highest prevalence is displayed in economically and technologically advanced, urbanized, and bureaucratized societies (Kleinman 1988, Warner 1985). Its phenomenology varies with cultural setting, with much higher rates of catatonia in India and of hebephrenia in Japan than in the West. Most important, the course and outcome of schizophrenia are markedly better in nonindustrialized countries, even when cultural differences in outcome assessment and in acuteness of presentation are taken into account (Sartorius et al. 1986, Lin and Kleinman 1988, Kulhara and Chakrabarti 2001). Variations in outcome are thought to be related in part to different attitudes toward persons with the disorder, a set of culturally patterned interactions studied under the rubric of expressed emotion (Jenkins and Karno 1992) (Table 39–2). Other cross-cultural variations with regard to schizophrenia include higher misdiagnosis among patients from devalued and ethnic minority groups (Good 1992/1993), differences in cultural and gender-related conceptions regarding the expression of emotion that complicate the assessment of flat affect (Karno and Jenkins 1997), and culturally syntonic experiences that may be mistaken for schizophrenic symptoms. The latter include the accepted appearance of hallucinations among the bereaved Native Americans (Hultkrantz 1979) or reports of perceptual alterations among the distressed Puerto Ricans (Guarnaccia et al. 1992).

Cross-cultural differences have also been detected in emotional processing among the German, American, and Indian subjects with schizophrenia. Face discrimination performance was most impaired in the Indian subgroup (Habel et al. 2000). Another study comparing the German natives and the Turkish immigrants with schizophrenia also found cross-cultural differences, this time in higher indices of hostile excitement and depression among the immigrant group (Haasen et al. 2001).

Clinical Vignette 1

A 28-year-old mainland Chinese man living in the US for several years was hospitalized in a psychiatric ward with delusions and hallucinations of 2 weeks duration. These began after he took up the practice of qi-gong, a form of meditation, as treatment for his severe intermittent backaches and chronic exhaustion. According to the patient, feelings of qi (“vital energy”) were circulating in the “wrong directions” in his body, and he heard the voices of supernatual beings commenting on how he should practice qi-gong. He denied depressed mood, appetite or weight changes, substance abuse, or a history of psychosis. The results of extensive medical evaluation, including electroencephalography and magnetic resonance imaging, were normal. Haloperidol follow-up information was unavailable because he did not keep his appointments after discharge.

Transient psychotic symptoms in connection with qi-gong practices are not uncommon, but duration for more than a few days is unusual. The patient’s picture meets criteria in the Chinese classification system for qi-gong-induced psychosis (a DSM-IV-TR culture-bound syndrome) and probably neurasthenia, because of his prodromal somatic symptoms. Brief duration of psychosis in the absence of confusion and emotional turmoil qualified the patient for a DSM-IV-TR diagnosis of psychotic disorder not otherwise specified (NOS), but if psychosis were to persist, a diagnosis of schizophreniform disorder could also be considered.

Mood Disorders

Contemporary cross-cultural research on mood disorders has focused on unipolar depression syndromes, revealing extensive cultural patterning as well as significant similarities. For example, the World Health Organization Collaborative Study on Depression found a core depressive syndrome in the five countries studied, but it also revealed substantial cross-cultural differences in symptom presentation, affect conceptualization, level of severity, and influence of acculturation, despite a methodology that tended to accentuate similarities at the expense of local differences (Marsella et al. 1985).

Source: Adapted from Mezzich et al. (1993).
Culture and other social factors, such as class and gender, influence the interpretation of and exposure to stressors that predispose to depression (Brown and Harris 1978). The specific characteristics of the dysphoria of depressive illness also vary cross-culturally. For example, among the Hopi in North America, feelings of guilt, shame, and sinfulness are separate experiences displaying distinct relationships to subtypes of depression (Manson et al. 1985). Whereas reports of irritability, rage, and “nervousness” are prominent descriptors of depressive affect among the Puerto Ricans and other Latinos (Lewis-Fernández 2002). The frequent combination of depression and anxiety noted around the world, particularly in primary care settings, has fueled the DSM-IV-TR proposal for a mixed anxiety-depression disorder (Katon and Roy-Byrne 1991).

In addition, most cross-cultural studies have found a significantly higher rate of somatic complaints associated with depression (and anxiety) among the non-Western groups than in the Western settings, including the presence of unique symptoms (e.g., “heat or water in the head” and “crawling sensation of worms and ants” in the Nigerian cultures) (Marsella et al. 1985, Ebigbo 1982). Emotional complaints are often present as well but may not be considered the source of distress or impairment. The mix of emotional and somatic symptoms has also been found to vary by sex in some studies (Clark et al. 1981, Guaraccia et al. 1989). For example, a study comparing the Puerto Ricans, Mexican-Americans, and Cuban-Americans on the Center for Epidemiologic Studies Depression Scale found that the women in all three groups tended to endorse depressive and somatic scale items together as a single factor. This happened significantly more often than was done by the men (Guaraccia et al. 1989).

Finally, the threshold at which dysphoria becomes disorder is affected by cultural factors. The 2-week duration criterion for major depression, an important proxy for pathological intensity, may vary among some non-Western groups. Manson et al. (1985) found that the Hopi identify five distinct indigenous syndromes related to depression, only one of which shares significant parameters with Western depressive disorder. This folk syndrome, however, differed from major depression in its average duration of 1 week, not 2, although still causing comparable morbidity. On the basis of this, duration criterion for major depressive disorder when it is used with the Hopi patients should be shortened (Manson et al. 1985). Conversely, in a study of the Bambuí community in Brazil, researchers were surprised to find depressive episodes averaging 1 month, higher than that observed in similar studies in many other societies (Vorcaro et al. 2001).

The substantial overlap of depression with anxiety, somatoform, and dissociative disorders implies a higher probability of under-recognition or misidentification of affective disorders in many ethnocultural groups (Kirmayer and Groleau 2001). These findings raise serious issues about the universality of the prototypical representation of depression in the North American psychiatry and the operational criteria of the depressive disorders, and tend to support the phenomenological expansion of the depression categories (Manson 1997, Kirmayer and Groleau 2001).

### Anxiety Disorders

The effect of culture on anxiety is similar to that on depression, especially since cross-cultural studies have shown a marked tendency for anxiety and depression to overlap (American Psychiatric Association 1994). Cultural factors affect the precipitants, symptom presentations, pathological thresholds, and specific syndrome criteria of the anxiety disorders (Good and Kleinman 1985). For example, the cross-cultural validity of criterion A for the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) generalized anxiety disorder (GAD) has been challenged because it restricts the diagnosis of chronic pathological anxiety to a disturbance stemming from undue worry in the absence of actual stressors or excessive worry after minor stress. This leaves out the much larger group of patients in developing societies and devalued minorities in the West who experience chronic pathological anxiety as a result of recurrent stress (Lewis-Fernández and Kleinman 1995).

Cultural and ethnic elements have been invoked to explain local differences in anxiety disorder prevalence that persist after controlling for other social factors. For example, the higher rate of simple phobia, social phobia, and agoraphobia among the African-Americans, as compared to whites (Neal and Turner 1991), has been attributed to the stress resulting from racial discrimination (Brown et al. 1990). In fact, the cross-cultural epidemiological literature reveals a complex pattern of similarities and differences with regard to the anxiety disorders, and opinions differ as to the role of culture in this process (Guaraccia and Kirmayer 1997). For example, it is presently unclear why the Mexicans born in Mexico, when compared with those born in the US, show a markedly lower rate of anxiety and other disorders. Suggested explanations include selective migrations, different thresholds for perceiving and reporting a
disorder stemming from distinct cultural interpretations of what constitutes a “hard life” and acceptable suffering, and a combination of both explanations (Shrout et al. 1982).

Multiple cross-cultural studies point to the coappearance of anxiety, depression, somatoform complaints, and dissociative symptoms among the non-Western groups. A markedly somatic idiom predominates, often in the form of culturally specific symptoms (Ebigbo 1982). These often coalesce distinctively as culture-bound syndromes characterized also by specific etiological factors, demographics, patterns of impairment, and help-seeking choices (Hughes et al. 1997). It is far from clear that this represents the comorbidty of the Western disorders rather than a different organization of pathological experience (Maser and Dinges 1992). Examples include ataque de nervios among the Latinos, koro in the Asian communities, and taijin kyofusho among the Japanese (Guarnaccia and Kirmayer in press). Each of these disorders exhibits significant differences that prevent simple one-to-one correlations with the established Western categories (Weiss 1996).

Clinical Vignette 3

A 42-year-old Puerto Rican man is referred to a regional mental health center by his own physician for treatment of chronic nervios (nerves). The patient describes a 4-year history of recurrent but intermittent symptoms of anxiety and depression since he hurt his back and was unable to return to agricultural work. He “awakens” with his symptoms several days a month but denies continuous symptoms for more than a few days. He feels partially handicapped by his symptoms, despite their intermittency, because he has been unable to sustain gainful work even after his back condition improved.

He describes exquisite reactivity to even minor stresses (e.g., watching crime news on television), resulting in acute nervousness, trembling, and crying. In addition, during his “bad days,” he reports anxiety, sadness, difficulty falling asleep, irritability, a wish to isolate himself, chest pressure, easy fatigue, dizziness (mareos), “thinking too much,” generalized worry that feels “out of control,” low self-esteem, occasional tearfulness, and hearing his name called out when alone and sensing the presence of someone behind him. On one of these symptomatic days, he “saw” a man dressed in black who approached him and then disappeared, causing him intense fear. His irritability can lead to aggressive outbursts in which he breaks objects and insults his family, which he calls ataque de nervios (nervous attacks). Later he regrets his actions during one of these episodes. He denies changes in his appetite, history of substance abuse, symptoms of formal thought disorder, panic attacks, and past exposure to trauma.

Because of the intermittent nature of the symptoms, which persisted despite improvement of the acute precipitating stressor, the patient received DSM-IV-TR diagnoses of anxiety disorder NOS and depressive disorder NOS.

Source: Case composed by Lewis-Fernández from unpublished clinical material.

Somatoform Disorders

In a survey of international use of DSM-III and DSM-III-R, somatoform disorders were among the more problematic diagnoses (Maser et al. 1991), probably because of their cross-cultural limitations (Kirmayer and Weiss 1997). First, many nosologies around the world do not distinguish between mood, anxiety, somatoform disorders, and dissociative disorders, because sufferers report single syndromes that run across boundaries of the diagnostic categories (Lewis-Fernández 1992). This is similar to the situation with depression, where a single description of the disorder has led to under-recognition and misidentification of depressive syndromes in many ethnocultural groups (Kirmayer and Groele 2001). Demarcating somatoform conditions in these settings may create artificial distinctions that confound accurate diagnosis. Examples include neurasthenia in China and other Asian settings, and nervios in Latin America (Lino 1989, Angel and Guarnaccia 1989).

Second, the idioms of distress of many societies rely on somatic complaints for the expression of nonpathological, personal, and social predicaments. Interpretations of these communication mechanisms as a somatoform disorder may result in overpathologization (Kirmayer and Robbins 1991). In addition, the use of somatic idioms varies according to intracultural factors, such as gender and class, which in turn may determine who receives a somatoform diagnosis. For example, conversion symptoms appear to be more common in rural and less educated sector of the non-Western societies, and particularly in family or social structures that allow few opportunities for protest (Kirmayer and Weiss 1997, Nichter 1981).

Third, the symptom lists of DSM-III-R and DSM-IV-TR do not canvass the rich variety of somatic symptoms reported in other parts of the world, such as the complaints of worms and ants in the head described earlier (Ebigbo 1982). Examples of other common somatic symptoms include chronic fatigue; heat in the feet, chest, or head; painful “gas” that moves from the abdomen around the flank to the back; “brainache”; and feeling presences when alone or among others.

Fourth, in most of the world, the degree to which symptoms are medically unexplained is difficult to ascertain owing to the marked limitation of diagnostic tests and medical personnel. Moreover, the high prevalence of endemic disease in the underdeveloped countries, often with protein and inchoate manifestations, may also confound the assessment of the somatoform disorders. This may result in overdiagnosis if organic causes are not identified, or underdiagnosis if organic explanations are uncritically accepted for systemic illness (Kirmayer and Weiss 1997).

Clinical Vignette 4

A 45-year-old Igbo woman in Nigeria presents to a local general medical clinic complaining of multiple somatic symptoms occurring every day, almost all day, for 7 months. Among other symptoms, she is particularly distressed by sensations of heat in her head and “inside” her body, heaviness in her head and hammer-like headaches, dizziness, palpitations, the sense that her head is “breathing” and the feeling that there is water or worms in it, “painful” vision and decreased visual acuity, generalized weakness, pain in the “marrow of the bones” in her hands and legs, sweating, easy fatigue, itching all over her body, and minor cramping.
Dissociative Disorders

Syndromes characterized by pathological dissociation are common worldwide, but the current concepts of dissociative disorders do not appear to account for their phenomenological variety (Lewis-Fernández 1992, Gonzalez et al. 1997). For example, a study performed in an outpatient psychiatric clinic in India found that more than 90% of dissociative disorder cases did not fulfill criteria for the specified categories, ironically receiving instead a DSM-III diagnosis of atypical dissociative disorder. Distressing trance states and possession trance episodes constituted most of these cases (Saxena and Prasad 1989). These instances of misdiagnosis again call to question the usefulness of some of the standard diagnostic categories of the North American psychiatry (Kirmayer and Groleau 2001). Many indigenous illness syndromes around the world display salient features of pathological dissociation. Some of these syndromes are characterized by involuntary possession trance—dissociative alterations in identity attributed to the invasion by external spirits or agents—distinguished from dissociative identity disorder by their episodic and remitting course, the nature and number of their alternative identities, and their gradual response to treatment. These syndromes have been identified in India, western Africa, China, Malaysia, Brazil, and the Caribbean, among many other settings (Lewis-Fernández 1994, Ward 1989, Spiegel and Cardena 1991).

Other dissociative syndromes are characterized by alterations of consciousness and memory, during which the person runs around in an agitated state (Arctic pibbloktq); attacks others indiscriminately (Malayo-Indonesian amok); undergoes convulsive movements, screaming fits, and aggressive acts toward self or others (Caribbean ataque de nervios); or lies as if dead, suffering from specific perceptual alterations; hears and understands what is happening but cannot see or move (“falling out” among the African-Americans in southern US, Bahamian “blackout,” and Haitian indisposition) (Gonzalez et al. 1997, Cardena et al, 2002, Weidman 1979). In a recent study, Lewis-Fernández et al. (1997) confirmed the association between ataque de nervios and dissociation. Among the female Puerto Rican psychiatric outpatients, ataque frequency was directly related to self- and clinician-ratings of dissociative symptoms and disorders. Of note, patients with and without ataque did not differ on measures of childhood trauma, which was uniformly high among subjects (Lewis-Fernández et al. 1997). The proposed dissociative trance disorder category in DSM-IV-TR would provide a Western nosological niche for these disorders, although not without the risk of over-pathologizing some culturally accepted instances of these behaviors (Lewis-Fernández 1992).

In fact, extensive cross-cultural research reveals that most dissociative experiences around the world are completely normal, usually forming part of religious and ritual events (Lewis-Fernández 1994). The Western emphasis on pathological experiences of dissociation that result from overwhelming trauma probably stems from the relative absence of normal dissociation among the dominant Western groups and from the acknowledgment by mental health professionals of the sequelae of physical and sexual abuse (Ross 1991, Martinez-Taboas 1991). Depersonalization, considered one of the most common psychiatric symptoms in the West (Steinberg 1991), is a greatly desired goal for Hindu yogis, revealing the substantial cultural patterning of dissociative experience (Castillo 1991).

**Clinical Vignette 5**

A 17-year-old recently married a Hindu woman starts to undergo episodes of pathological possession trance 2 weeks after moving to her mother-in-law’s house in a different village in India. Her first episode is preceded by a generalized convulsion, rolling on the ground, loud screaming, and a period of unconsciousness. On regaining semiconsciousness with a start, the woman speaks and behaves as the ghost of a dead cousin. Shouting loudly, she berates her in-laws and her new husband, who try to force the spirit out by pinching and other noxious stimuli. Minutes later, the woman again enters near-unconsciousness, moaning softly, signaling the temporary departure of the spirit. During a period of hours, she lapses between near-unconsciousness and full possession several times.

These recent attacks recur for 3 weeks, with mounting aggressiveness, despite the ministrations of traditional healers, who diagnose “possession syndrome.” The patient improves slightly only after her father travels to see her and takes her back on an extended visit to her family of origin following up a referral to a regional healing temple.

**Source:** Adapted from Lewis-Fernández (1994).

**Sexual Disorders**

Research on cross-cultural influences on sexual disorders is limited, owing to the lack of uniform descriptive methodology and to the fact that the major ethnic minorities in the US do not seek medical treatment for this class of complaints (Davis and Herdt 1997). Some cross-cultural studies have concluded that the paraphilias as currently characterized in the DSM-IV-TR are determined by specific features of the Western society, such as demographical size and complexity (whereby individuals may escape social sanction through anonymity), the nonavailability of partners, and the primacy of masturbatory activities as sexual outlets (Rooth 1973, Gebhard 1971). Despite a few small clinical studies that found similar rates of sexual dysfunctions among the
African-American populations (Fisher 1980, Finkle and Finkle 1978), most cross-cultural research suggests that sexual response is influenced by cultural and ethnic considerations. Racist stereotypes, machismo, anxiety about infertility, and the tendency toward somatization of mood disorders as impotence have been cited as etiological factors of sexual dysfunction in the African-American and Latino populations (Wyatt 1982, Espin 1984). In addition, the ethnographical literature shows that the standards for sexual competence differ across the cultural spectrum and that many societies display a more flexible approach to issues of sexual orientation than is assumed by the diagnostic categories (Davis and Whitten 1987, Herdt 1990).

This cross-cultural diversity complicates the assessment of the sexual disorders. At present, it is unclear whether certain culture-bound syndromes involving sexual organs, such as koro among the Asians (characterized by the fear of genital retraction) or dhat in India (involving obsession or anxiety about semen loss), should be categorized among the sexual or the somatoform disorders (Davis and Herdt 1997).

**Eating Disorders**
Research has disclosed a significant cultural effect on the patterning and distribution of the eating disorders. An important determinant appears to be the Western premium on thinness as an esthetic and moral value (Ritenbaugh 1982, Nichter and Nichter 1991, Banks 1992). Cases of eating disorder have been found in many non-Western societies and several ethnic minorities in the US, but their presenting features often differ somewhat from the DSM-IV-TR criteria for anorexia nervosa and bulimia nervosa (Shisslak et al. 1989).

Groups at high risk include those experiencing rapid acculturation to the Western society, such as immigrants or those living in areas undergoing accelerated industrialization (Ritenbaugh et al. 1997). For example, one study found a 12% prevalence of DSM-III eating disorders among the Egyptian female college students in London and no evidence of these conditions among a similar sample in Cairo (Nasser 1986). Although it is as yet unclear exactly how acculturation predisposes the non-Caucasians to eating disorders, as a rule these conditions are more prevalent among the Caucasians than persons of other ethnic backgrounds (Wildes et al. 2001). Bulimia nervosa appears more common than anorexia nervosa among the US minorities and is often associated with higher than average weight, female sex, and sometimes, older age, for example, among the American Indian groups (Rosen et al. 1988). Anorexia nervosa has been found among lower socioeconomic class samples in several cultures but often characterized by atypical features, such as the absence of distorted body image or of the fear of gaining weight (Suematsu et al. 1985, Lee et al. 1989).

Cross-cultural studies have proposed more flexible diagnostic criteria for anorexia nervosa so that abdominal fullness, epigastric pain, or distaste for food may be accepted instead of intense fear of weight gain to account for the severe restriction of food intake or other weight-losing behavior (Lee 1991).

**Adjustment Disorders**
The effect of culture on the adjustment disorders is pervasive. Culturally based interpretations are essential to the appraisal of the repertoire of behavioral and emotional responses that pattern both normal and disordered reactions to stress (Jenkins and Kinzie 1997). Whereas some experiences are uniformly stressful (e.g., natural disaster), others may make sense only within particular cultural contexts (e.g., facing deadlines, witchcraft accusations) (Fabrega and Mezzich 1987). In addition, the judgment of what constitutes a maladaptive response to a stressor must be made in relation to what exceeds cultural norms (Kleinman 1988).

Diagnosis of an adjustment disorder may be a particular problem among refugee populations. These groups have undergone distressing experiences, but their intensively challenged coping styles may be unknown to caregivers in the host country (Beiser 1996).

**Personality Disorders**
The current configuration of the personality disorders has received substantial cross-cultural challenge. Even the basic concept of personality as a set of individual internal traits is considered inseparable from the Western cultural assumptions on individuality by many authors (Lewis-Fernández and Kleinman 1993). Difficulties in the reliable assessment of these disorders within the Western cultures may be due to the degree to which these conditions are determined by social and contextual factors. These factors include adaptational strategies toward adverse communal environments (including the relative value of aggression or avoidance), family-based customs and traditions, occupational and educational options, and cultural methods of child-raising (Alarcon and Foulks 1997). It is striking, for example, that the antisocial personality disorder is nearly absent among the Hutterites, an ethnoreligious enclave living for more than a century in the US and Canada (Favazza 1985). Intra-cultural diversity may be more important in this respect than cross-cultural difference. For example, in his studies of affective and personality disturbances among the Inuit and the Yoruba, Leighton (1981) was unable to disentangle cultural influences from “the much more powerful effects” of gender, age, and class.

Epidemiological assessment of DSM-III antisocial personality disorder has been performed as part of the Epidemiological Catchment Area study using a clearly operationalized survey instrument, the Diagnostic Interview Schedule (Robins et al. 1984). This yielded similar prevalence rates in the US and Puerto Rico (Canino et al. 1987). However, low reliability rates for the diagnosis of personality disorders across standardized instruments raise serious doubts about the validity of this aspect of the Epidemiological Catchment Area study data (Perry 1992). One World Health Organization study was able to identify cases of most of the International Classification of Diseases personality disorders in 15 urban clinic samples in Africa, Asia, North America, and Europe (Paris 1991), but the cross-cultural validity of the definitions of these categories had been criticized earlier by Shepherd and Sartorius (1974).

**The Case of Culture-Bound Syndromes and Idioms of Distress**
Investigation of so-called culture-bound syndromes was geared for decades toward incorporation of these “exotic” categories into the Western nosologies (Simons and Hughes 1985). The term “culture-bound” (Table 39–3) was used to
describe a certain number of psychiatric disorders whose phenomenologies made them distinct from the Western categories and that theoretically could be singled out as unique to a particular cultural setting (Hughes et al. 1997). The clear implication was that the Western categories were not culture-bound but rather universal, and that proper characterization would disclose a translation key for specific non-Western syndromes. However, these conditions have been studied more critically to understand instead the culture-bound nature of the Western classification schemes themselves and to enable the appropriate treatment of patients whose understandings and presentation of illness conform to these indigenous categories (Good 1994, Good and Delvecchio Good 1982).

Contemporary cultural psychiatry recognizes that all classification schemes are inherently cultural and subjects Western nosologies to the same kind of social analysis that it continues to apply to the indigenous nosologies (Lewis-Fernández and Kleinman 1995). In this modern sense, “cultural-bound syndrome” is an inherited and controversial term that is used in practice to describe psychiatric categories, whether they are part of the Western or non-Western nosologies, on whose emergence, manifestation, or course culture is thought to exert a particularly strong influence (Hahn 1985, Guarnaccia 1993). The term continues to refer to relatively consistent illness categories with characteristic courses (“syndromes”) and specific labels, some of which are discussed in this chapter (e.g., amok, taijin kyofusho, anorexia nervosa). The organizing principle that unifies a syndrome conceptually can be (1) a collection of symptoms, which can follow diverse classificatory schemes (descriptive); (2) a cause, including an immediate precipitating context (etiological); or (3) a response to treatment (Good and Delvecchio Good 1982).

“Idiom of distress” is a newer term, which was coined to refer to a more general level of analysis (Nichter 1981). Rather than denoting specific syndromes, the term refers to the more general illness “languages” of social groups, the culturally preferred ways of expressing distress, such as by somatic complaints, psychologizing explanations, possession or witchcraft terminology, oppositional or violent behavior illnesses due to “nerves,” or attributions of inexplicable misfortune. In this sense, a given idiom of distress, such as somatization, can be expressed as multiple culture-bound syndromes such as ataques de nervios, neurasthenia, “brain fag,” and so on. DSM-IV-TR presented a substantial list of culture-bound syndromes and idioms of distress in one of its appendices.

Contemporary use of this terminology allows us to understand certain difficulties in the integration of the Western and non-Western categories of psychiatric illness (Lewis-Fernández 1992, Wig 1983). First, the Western nosologies are based at present nearly exclusive on descriptive parameters. Wary of “theoretical” causes, our current diagnostic system privileges a formal definition of psychopathological processes. Most indigenous nosologies, on the other hand, distinguish illness from normality at least as much on the basis of contextual characteristics as on descriptive ones. These include assessments regarding appropriateness of the symptom in the particular setting at the specific time in question, the relative sufficiency of precipitating stressors, and the nature and quality of the human relationships of the sufferer. These discrepancies between the organizing principles of the Western and non-Western nosologies prevent an easy consolidation of psychopathological criteria across cultures.

Second, nosologies also differ in the configurations of their phenomenologies (Kleinman 1988, Weiss 1996, Good and Delvecchio Good 1982). The symptoms of many culture-bound syndromes, such as amok in Malaysia, or ataques de nervios in Puerto Rico, are composed of a variety of behavioral and experiential elements that are considered by the Western nosologists to belong to separate diagnostic categories. The characteristic presentations of these conditions exhibit diverse combinations of dissociative, psychotic, anxiety, depressive, characterological, and somatic symptoms (Lewis-Fernández 1992). Significant phenomenological variation occurs among individual cases, which are nevertheless unifying under a single nosological label.

These differences in definitions of illness and phenomenological organization between the Western and non-Western categories ensure that the two nosologies are overlapping as global systems. From the psychiatric perspective, a cohort of individuals identified by a cohort indigenous label will prove to be diagnostically heterogeneous or even nonpathological. The obverse is that almost homogeneous psychiatric cohorts will appear locally verse. Anomographical, one-to-one relationship between the Western and non-Western nosologies appears, thus unattainable (Weiss 1996). What is achievable is the systematic characterization of individual cases of persons suffering from culture-bound syndromes in terms of the Western categories of psychiatric illness, retaining at the same time an account of their distinct definitions.
of illness, idioms of distress, unique symptoms, and other associated factors in the form of a cultural formulation (Mezzich and Good 1997) (Table 39-4). This iterative process of translation will result eventually in a comprehensive cultural psychiatry that integrates diverse local and professional classifications of psychiatric illness with the goal of more effective communication and care of patients.

Table 39-4 Components of the DSM-IV-TR Outline for a Cultural Formulation

| Cultural identity of the individual |
| Cultural explanations of the individual’s illness |
| Cultural factors related to psychosocial environment and levels of functioning |
| Cultural elements of the relationship between the individual and the clinician |
| Overall cultural assessment for diagnosis and care |

In spite of the importance of including culture-bound syndromes in the DSM-IV-TR, Guarnaccia and Rogler (1999) warn that important methodological issues remain unaddressed, since DSM-IV-TR does not include a system of norms to delimit the range of psychiatric disorders that relate to particular culture-bound syndromes, nor include these cultural conditions within the established disorder categories.

Conclusion

The importance of culture in the understanding of psychopathology is revealed by the literature summarized in this chapter. However, future studies must evolve to include psychological and psychiatric measures that are relevant and appropriate for distinct cultural groups, since many cross-cultural studies utilize the Western concepts to explain the modes of expression of psychopathological manifestations (Kirmayer and Groleau 2001), ways of seeking aid, use of mental health services, or treatment outcome, without taking into account their close relationship with cultural factors (Aneshensel and Phelan 1999). At the same time, new possibilities are emerging for the application of cultural information to diagnostic systems and the diagnostic process. This chapter has focused on some of the most conspicuous contributions aimed at enhancing the cultural suitability of DSM-IV-TR, and thus on the use of diagnostic categories and criteria in multicultural settings. Other contributions, such as the glossary of culture-bound syndromes and idioms of distress and the guidelines for a cultural formulation, have been referred to succinctly. Cultural developments are also being worked into the family of classifications of the ICD-10 (Mezzich 1995). All these efforts promise to increase the applicability and usefulness of the new diagnostic systems for our multicultural world. Further, they may encourage psychiatrists and the field as a whole to stay focused on the person of the patient and his or her context to augment the validity of diagnosis and the effectiveness of clinical care.

Disorders
Introduction
There is a natural human predilection to categorize and classify for simplifying and organizing the wide range of observable phenomena and experiences that one is confronted with, thus facilitating both their understanding and their predictability. Many (if not most) of the mental disorders that afflict contemporary individuals have occurred in antiquity. For example, the first recorded depiction of mental illness dates to 3000 BC Egypt with a description of the syndrome senile dementia attributed to Prince Ptah-hotep (Mack et al. 1994) The current system for the diagnosis of mental disorders, the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) (American Psychiatric Association 1994) is just the latest example from the long and colorful history of psychiatric classification. Although there was a more recent Text Revision, DSM-IV-TR (American Psychiatric Association 2000), we will refer to DSM-IV as the “current” version since it primarily differs from DSM-IV-TR with respect to the textual descriptions of the disorders. The classification, diagnostic terms, and virtually all of the diagnostic criteria are identical (First and Pincus 2002).

Goals of a Classification System
Perhaps the most important goal of a psychiatric classification is to allow mental health practitioners and researchers to communicate more effectively with each other by establishing a convenient shorthand for describing the mental disorders that they see (First 1992). For example, saying to a colleague that a patient has major depressive disorder can convey a great deal of information in only a few words. First of all, it indicates that depressed mood or loss of interest is a central aspect of the presenting problem and that the depression is not the kind of “normal” mood fluctuation that lasts for only a few days but rather that it persists every day for an extended period of time, at least 2 weeks. Furthermore, one can expect to find a number of additional symptoms occurring at the same time, like suicidal ideation and changes in appetite, sleep, energy, and psychomotor activity. Finally, information is also communicated about what is not to be found in this patient—specifically, that the depression is not caused by the direct physiological effects of alcohol, other drugs, medications, or a general medical condition, that the depression does not represent simple bereavement, and that there is no history of schizophrenia or manic or hypomanic episodes.

DSM-IV also facilitates the identification and management of mental disorders in both clinical and research settings. Most of the DSM-IV diagnostic labels provide considerable and important predictive power. For example, making a diagnosis of bipolar disorder suggests the choice of treatment options (e.g., mood stabilizers), that a certain course may be likely (e.g., recurrent and episodic), and that there is an increased prevalence of this disorder in family members. By defining more or less homogeneous groups of individuals for study, DSM-IV can also further efforts to understand the etiology of mental disorders. The operationalized definitions in the manual have been a reflection of, and a major contribution to, the development of an empirical science of psychiatry. DSM-IV also plays an important role in education. In its organization of disorders into major classes, the system offers a structure for teaching phenomenology and differential diagnosis. DSM-IV is also useful the psychoeducation of patients and their families by showing patients that their pattern of symptoms is not mysterious and unique but rather something that has been identified and studied in others.

Approaches to Classification
Etiological vs. Descriptive
Historically, there have been two fundamental approaches to formulating systems of psychiatric classification: etiological and descriptive (First 1994). Etiology-based classification systems organize categories around pathogenetic processes so that disorders corresponding to a particular category share the same underlying cause. Although such systems tend to have relatively few categories and therefore...
are easy to use, their ultimate value is constrained by the limited extent to which underlying etiological factors have been elucidated. For example, the 16th century Swiss physician Paracelsus developed a classification system in which he divided psychotic presentations into three types of disorders on the basis of the presumed etiology. The first category, vesania, for disorders caused by poisons, is analogous to current-day substance-induced disorders. Insanity, for diseases caused by heredity, is analogous to modern disorders such as schizophrenia and bipolar disorder, which appear to have a strong familial component. His category of lunacy, which described a periodical condition influenced by the phases of the moon, has no analogous condition today because we know that the phases of the moon are not a direct cause of psychopathological conditions.

Because the etiological basis for most psychiatric conditions remains unknown, etiological classification systems tend to be based instead on a particular conceptualization of or theory about the process of mental disorders. Although such classifications may be heuristicly useful to proponents of the particular conceptualization that forms the basis of the system, they are often considerably less useful for proponents of different etiological principles, which greatly limit their utility. For this reason, a descriptive approach to classification has proved to be of greater utility given our current level of understanding. The descriptive approach aims to eschew particular etiological theories and instead relies on clinical descriptions of presenting symptoms. This approach, advanced by the work of the 19th-century psychiatrist Emil Kraepelin (Kraepelin 1992) formed the basis for the system of classification of the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) introduced in 1980. As a result, DSM-III and its successors, the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) and DSM-IV, have proved to be useful in a variety of different settings and by psychiatrists of widely different backgrounds and conceptual orientations.

**Syndrome vs. Symptom**

Given that the manual lacks a specific etiological conceptualization, what is its organizing principle? The fundamental element is the syndrome, that is, a group or pattern of symptoms that appear together temporally in many individuals (First et al. 1992). It is assumed that these symptoms cluster together because they are associated in some clinically meaningful way, which perhaps may reflect a common etiological process, course, or treatment response. Alternatively, individual symptoms could have been emphasized as the fundamental conceptual entities so that a person’s disorder would be classified by enumerating all of his or her relevant symptoms. In fact, historically, there have been classifications that have been symptom based. For example, Boissier de Sauvages proposed a medical classification that arranged presenting symptoms into numerous classes, orders, and genera, comparable to the classification of plants and animals. This approach generated 2,400 disorders, each of which was essentially a symptom.

Although it was hoped that the syndromes identified in the DSM represented relatively homogeneous subpopulations of patients, over the past two plus decades since the publication of these definitions in DSM-III in 1980, the goal of discovering common etiologies for each of the DSM-defined syndromes has remained elusive. Epidemiologic and clinical studies have shown extremely high rates of comorbidities among the disorders, undermining the hypothesis that the syndromes represent distinct etiologies. Furthermore, epidemiologic studies have shown a high degree of short-term diagnostic instability for many disorders. With regard to treatment, lack of specificity in treatment response is the rule rather than the exception. The efficacy of many psychotropic medications cuts across the DSM-defined categories. For example, the selective serotonin reuptake inhibitors have been demonstrated to be efficacious in a wide variety of disorders from many different sections of the DSM, including Major Depressive Disorder, Panic Disorder, Obsessive–Compulsive Disorder, Dysthymic Disorder, Bulimia Nervosa, Social Anxiety Disorder, Post-traumatic Stress Disorder, Generalized Anxiety Disorder, Hypochondriasis, Body Dysmorphic Disorder, and Borderline Personality Disorder. Results of twin studies have also contradicted the DSM assumption that separate syndromes have a different underlying genetic basis. For example, twin studies have shown that Generalized Anxiety Disorder and Major Depressive Disorder may share the same genetic risk factors (Kendler 1996, Kendler et al. 2007) and evidence from molecular genetics research (Berrettini 2000, Berrettini 2003) indicates that three of the putative susceptibility loci associated with DSM-defined bipolar disorder also contribute to the risk of DSM-defined schizophrenia.

Given these clear limitations in the syndromal approach, it is important that users of the DSM resist the temptation to reify the DSM diagnostic categories as if they were actual diseases. They are best viewed as clinically useful constructs that are helpful in facilitating communication and record keeping and in selecting treatment. As more information about the causes of mental disorders become evident over the next decades, it is more than likely that the syndromal approach will be replaced by a classification system that is more reflective of the underlying etiology and pathophysiology. A hypothetical example (Table 40–1) of what such a classification system might look like is described in the white paper on Basic Neuroscience and Genetics, (Charney et al. 2002) included as part of the DSM-V Research Agenda. (Kupfer et al. 2002b).

### Categorical vs. Dimensional

The diagnoses included in DSM-IV are defined categorically, that is, diagnostic criteria are provided that indicate whether an individual’s clinical presentation either meets or does not meet the diagnostic criteria for a particular disorder. This method of classification is similar to what is used in the rest of medicine, that is, a patient either has or does not have pneumonia, etc. This tendency to define illness in terms of categories is undoubtedly due to the fact that it is reflective of basic human thought processes, embodied by the use of nouns in everyday speech to indicate categories of “things” (e.g., chairs, tables, dogs, cats, etc.).

In principle, however, variation in symptomatology can be represented by a set of dimensions rather than by multiple categories. An example of this in medicine is blood pressure, which is measured along a continuum from low to high. (It only becomes categorical when we apply the label “hypertension” to indicate that a patient has a significant
simultaneous DSM diagnoses) is arguably a direct result of excessive comorbidity (i.e., an individual receiving multiple diagnoses. First of all, the commonly observed phenomena of comorbidity (Goldberg 1996, Widiger and Samuel 2005). Disorders that seem to merge imperceptibly both into one another and into normality with no demonstrable natural boundaries. For example, Wittenborn, Holzberg and Simon (Wittenborn et al. 1953) developed a multidimensional representation of the phenomena of psychotic illness nearly 50 years ago and since then others have developed dimensional models to portray the symptomatology of depressive and anxiety disorders, schizophrenia, personality disorders, and even the entire range of psychopathology (Mineka et al. 1998, Peralta and Cuesta 2000, Peralta et al. 2002, Clark 2005, Krueger et al. 2005, Watson 2005). While a categorical approach to classification has important heuristic appeal, it may not represent the true state of things. Implicit in the categorical approach is an assumption that mental disorders are discrete entities, separated from one another, and from normality, either by recognizable distinct combinations of symptoms or by demonstrably distinct etiologies. While this has been shown to be the case for a small number of conditions (Down’s syndrome, fragile X syndrome, phenylketonuria, Alzheimer’s and Huntington’s diseases and Jacob-Creutzfeldt disease, for example), there is little evidence supporting the applicability of this model for most other psychiatric disorders. Indeed, in the last twenty five years, the categorical approach has been increasingly questioned as evidence has accumulated that so-called categorical disorders like major depressive disorder and anxiety disorders, and schizophrenia and bipolar disorder seem to merge imperceptibly both into one another and into normality with no demonstrable natural boundaries (Goldberg 1996, Widiger and Samuel 2005).

Dimensional approaches do have some clear advantages. First of all, the commonly observed phenomena of excessive comorbidity (i.e., an individual receiving multiple simultaneous DSM diagnoses) is arguably a direct result of having a categorical system with more than 250 categories. (First 2005b) A dimensional approach, which would characterize an individual’s psychopathology by indicating the extent of his or her psychiatric symptomatology across a number of dimensions, virtually eliminates apparent comorbidity. For example, consider an individual who presents with depression, anxiety, and social avoidance. Using the DSM-IV categorical system, criteria might be met for three diagnoses (i.e., major depressive disorder, social phobia, and generalized anxiety disorder) thus warranting a diagnosis of all three disorders on Axis I. A dimensional approach may simply indicate that the person has “high scores” on the depression, anxiety, and social avoidance dimensions. Another advantage of the dimensional approach is that it avoids setting particular thresholds for distinguishing between pathology and normality. Rather than categorically saying that an individual has major depressive disorder, a dimensional approach might say that the person is high on the depression dimension.

Dimensional approaches have other advantages as well. Research studies using dimensional scales as end points have much greater power to detect differences in groups than do studies focusing on changes in dichotomous categories (Cohen 1983, Kraemer et al. 2004). Furthermore, continuous dimensions more closely model the lack of sharp boundaries between disorders and between disorder and normality and can be developed using empirical methods that would facilitate research into the underlying etiology and pathophysiology of mental disorders (Goldberg 1996, Smoller and Tsuang 1998). Finally, dimensions can be helpful in indicating the severity of the disorder, which is clinically-relevant in making treatment decisions. For many disorders in the DSM-IV the range of appropriate treatments is related to the severity of the disorder. (Andrews et al. 2007). For example, while either cognitive therapy alone or antidepressant medication alone are both reasonable options for the treatment of mild to moderate major depressive disorder, cognitive therapy by itself would not be an appropriate option for the treatment of severe forms of major depressive disorder. In such cases, treatment options would include one or more antidepressant medications or electroconvulsive therapy.

There are some practical problems that may potentially limit the utility of adopting a dimensional approach (First 2005a). First of all, clinicians are accustomed to thinking in terms of diagnostic categories, and the existing knowledge base about the presentation, etiology, epidemiology, course, prognosis, and treatment is based on these categories. Furthermore, decisions about the management of individual patients (e.g., whether to treat and with what type of treatment) are also much easier to make if the patient is thought of as having a particular disorder (with its associated prognostic and treatment implications) rather than as a profile of scores across a series of dimensions. One of the challenges for the future is to craft dimensional approaches that have sufficient clinical utility to warrant the increased complexity. (First and Westen 2007).

**History of the DSM Classification System**

**DSM I and DSM-II**
The predecessors of DSM-IV arose from the need to develop a classification system of mental disorders for statistical,
epidemiological, and reporting purposes. The first official international classification of mental disorders, the sixth revision of the International Classification of Diseases (ICD-6), was considered unacceptable by most countries because of its heavy reliance on unproven etiological concepts. The Diagnostic and Statistical Manual of Mental Disorders, First Edition (DSM-I) was published in 1952 as an alternative to ICD-6 and included glossary definitions of the various disorders (American Psychiatric Association 1952). The Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II) (American Psychiatric Association 1968) was published in 1968. Like DSM-I, DSM-II retained many etiological concepts (e.g., neuroses).

**DSM-III**

After reviewing early drafts of ICD-9 in the early 1970s, the American Psychiatric Association opted to develop DSM-III (American Psychiatric Association 1980) because of concerns that the international nature of the ICD-9 resulted in inconsistent terminology and definitions and that the subtyping was inadequate for clinical and research use. DSM-III represented a major paradigm shift from the etiologically based frameworks of DSM-I and DSM-II. It adopted a descriptive approach that was meant to facilitate communication between mental health professionals operating under various theoretical orientations that continue to flourish in the psychiatry and psychology.

Two innovations were introduced into DSM-III. Each DSM-III disorder was defined by use of explicit diagnostic criteria, which greatly improved the reliability of the system and provided researchers with well-defined categories for scientific study. DSM-III also included a multiaxial system for evaluation that facilitated the use of a biopsychosocial model of evaluation by separating (and thereby calling attention to) developmental and personality disorders (Axis II), physical conditions (Axis III), stressors (Axis IV), and level of adaptive functioning (Axis V) from the presenting diagnoses (Axis I).

**DSM-III-R**

In 1987, DSM-III-R was published (American Psychiatric Association 1987) although originally intended only as a fine-tuning to correct inconsistencies and problems identified after the publication of DSM-III (Boyd et al. 1984, Spitzer and Williams 1987), more substantive changes were made, many reflecting new evidence not available to the developers of DSM-III. Although the publication of DSM-III-R demonstrated that the system is self-correcting, DSM-III-R has been criticized as being too much of a change occurring too soon after the adoption of DSM-III.

**DSM-IV**

DSM-IV was envisioned as a modification and refinement of previous editions of the manual rather than a radical reconceptualization (Frances et al. 1989, Frances et al. 1990). The most significant change in DSM-IV is in the process by which DSM-III-R was revised to produce DSM-IV (Widiger et al. 1991). Prior revision efforts were guided almost exclusively by expert consensus. Although these experts were certainly familiar with the then-current state of knowledge about the psychiatric disorders, their decisions were subject to potential biases. In contrast, whenever possible, DSM-IV decisions were based on a systematic review of the then-current empirical database.

The method used to establish an empirical basis for changes in DSM-IV was divided into three stages. As a first step, the approximately 150 questions most deserving consideration for DSM-IV were identified (Widiger et al. 1990). Each of these then received an extensive and systematic review of the literature to determine what evidence was available and what additional evidence would need to be collected to support possible changes. One obvious shortcoming of relying on the literature reviews was that many important questions arose that were not addressed by the published literature. The second stage of the process was to conduct a series of approximately 40 data reanalyses of previously compiled data sets to supplement the evidence available from published studies. Although useful in generating new criteria sets for DSM-IV, the data reanalyses were limited by the fact that the data were collected before the DSM-IV process. Therefore, a series of 12 focused field trials were conducted (Table 40–2). Each field trial drew subjects from at least five different sites (with a minimum of 50 patients per site) (Kline et al. 1993). The field trials served to test the performance characteristics of the proposed criteria sets and to compare them with the DSM-III, DSM-III-R, and ICD-10 criteria sets. A summary of the results of the empirical review process as well as the rationale for the changes in DSM-IV is published in the four volume *DSM-IV Sourcebook* (Widiger et al. 1994, Widiger et al. 1996, Widiger et al. 1997, Widiger et al. 1998).

</tbody>
</table>

The following example serves to illustrate this three-stage process. One of the main goals of the DSM-IV revision process was to improve the clinical utility of the criteria sets. In this regard, several of the DSM-III-R criteria sets had been identified as being particularly difficult to apply in clinical settings. One of the most cumbersome criteria sets was that for somatization disorder, which provided a list of 35 different unexplained physical symptoms, of which at least 13 were required for a diagnosis. A literature review was first conducted to investigate the performance characteristics of the DSM-III-R criteria set. It demonstrated, as expected, that the DSM-III-R definition was among the most reliable and valid in the manual. Any attempt to modify the criteria set would therefore have to result in a criteria set that defined the same group of patients as did DSM-III-R and be comparably reliable. A more user-friendly criteria set
was generated through the data reanalysis process. Data sets of patients with somatization disorder were pooled, and different diagnostic algorithms were investigated. The resulting proposed criteria set required symptoms for a period of several years that occur in the following pattern: at least four pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one conversion symptom. To ensure the generalizability of this proposed criteria set, a focused field trial was conducted that compared this simplified definition with the original DSM-III-R definition, along with DSM-III, ICD-10, and the historical definition of Briquet’s syndrome. The field trial found that all of the definitions identified essentially the same group of patients with comparable reliability, providing empirical support for the DSM-IV decision to replace the DSM-III-R criteria set for somatization disorder. (Yutzy et al. 1995).

DSM-IV-TR

During the DSM-IV revision process, some criticisms were voiced about the rapid pace of DSM revisions, arguing that undertaking an extensive revision of the classification every 7 years was disruptive to researchers and was not necessarily justified by the pace of psychiatric research. (Zimmerman 1988). DSM-IV was timed for publication in 1994 in order to coincide with the publication of ICD-10 in 1992. In the absence of any externally imposed time frame (given that there was no anticipated date for starting work on ICD-11) it was decided that the interval between DSM-IV and the next revision would be greatly extended to at least 16 years (i.e., DSM-V will not come out until 2012). One consequence of this is the effect on the currency of the DSM-IV text, which was based on a literature review that extended only to mid 1992. Thus, in order to maintain continued clinical utility and educational value, a revision of the DSM-IV text was begin in 1996 (First and Pincus 2002) Following the DSM-IV precedent of only making changes if supported by data, changes to the text were made based on a comprehensive review of the literature relevant to the text categories that was published since 1992. The text revision (American Psychiatric Association 2000), called “DSM-IV-TR” to distinguish it from DSM-IV, was published in June 2000.

DSM-V

In advance of starting work on DSM-V, a DSM-V research planning process was initiated in order to (1) stimulate research that will enrich the empirical data base prior to the start of the DSM-V revision process and (2) devise a research and analytic agenda that would facilitate the integration of findings from animal studies, genetics, neuroscience, epidemiology, clinical research, cross-cultural, and clinical services research, which will lead to the eventual development of an etiologically based scientifically sound classification system (Kupfer et al. 2002a, Regier et al. 2002).

The first phase of the research planning process involved the development of a series of white papers. Rather than organizing the white paper workgroups around the traditional diagnostic categories, the workgroups which were set up to develop the white papers focused instead on cross-cutting issues, which included (1) a basic nomenclature workgroup, focusing on a variety of issues that had to do with the way disorders are classified in the DSM, (2) a neuroscience and genetics workgroup whose focus was to develop a basic and clinical neuroscience and genetics research agenda to guide the development of a future pathophysiological based classification, (3) a developmental science workgroup which outlined a research agenda to inform developmental aspects of the diagnostic classification, (4) a workgroup focusing on two major gaps in the DSM-IV, namely inadequacies in the classification of personality disorders and of relational disorders, (5) a mental disorders and disability workgroup which focused on disentangling the concepts of symptom severity and disability, and a (6) culture and psychiatric diagnosis workgroup which considered cross-cultural issues in diagnosis and classification.

The first six white papers were published as a monograph in 2002 (Kupfer et al. 2002b). Three additional white papers, one focusing on gender issues, one focusing on diagnostic issues in the geriatric population, and one focusing on mental disorders in infants and young children were commissioned subsequently and appear in a recently published second volume of the research agenda. (Narrow et al. 2007).

The second phase of the DSM-V Research Planning Process consisted of eleven research planning conferences (plus a methods conference) from 2004–2007 under the title “The Future of Psychiatric Diagnosis: Refining the Research Agenda.” Unlike the white papers in the first phase which focused on general cross-cutting issues, these conferences for the most part focussed on specific diagnostic topics. The primary goals of these conferences were to stimulate the empirical research necessary to allow informed decision making regarding crucial diagnostic deficiencies identified in DSM-IV and ICD-10 and to promote international collaboration in order to increase the likelihood of developing a future unified DSM/ICD (i.e., each conference have two co-chairs, one from the US and the other outside the US, each included an equal number of the US and international participants, and half the conferences took place outside of the US). The eleven diagnostic-topics focused conferences covered Dimensional Approaches Personality Disorders (December 2004, Arlington, VA, USA); Substance-Related Disorders (February 2005, Rockville, MD); Stress-Induced and Fear Circuitry Disorders (June 2005, Arlington, VA, USA); Dementia (September 2005, Geneva, Switzerland), Deconstructing Psychosis (February 2006, Arlington, VA, USA); Obsessive–Compulsive Spectrum Disorders (June 2006, Arlington, VA, USA); Dimensional Approaches to Diagnosis (July 2006, Bethesda, MD, USA); Somatic Presentations (September 2006, Beijing, China); Externalizing Disorders of Childhood (February 2007, Mexico City, Mexico); Comorbidity of Anxiety and Depression (June 2007, London, UK); and Public Health Implications (September 2007, Geneva, Switzerland).

Based on the material presented at these research conferences, it is unlikely genetics, neuroimaging findings, or biological markers will be incorporated into the diagnostic criteria for disorders in DSM-V. Evidence from the conferences does strongly support the incorporation of dimensional approaches along with categorical approaches in DSM-V; the challenge will be to formulate dimensions that will be useful to both researchers and clinicians. Finally, developmental approaches to diagnoses will be more prominent, with definitions being modified to reflect differing presentations across the life span.

**DSM-IV Overview**

The remainder of this chapter provides an overview of the DSM-IV multiaxial system as well as a presentation of some of the organizational principles of the various diagnostic groupings included in the DSM-IV classification. The other chapters in the Disorders section of this textbook are organized according to their presentation in the DSM-IV Classification and provide detailed information regarding the diagnosis, etiology and pathophysiology, epidemiology, course, and treatment of these DSM-IV disorders.

**DSM-IV Multiaxial System**

The multiaxial system was first introduced by DSM-III (Williams 1987) in order to encourage the clinician to focus his or her attention during the evaluation process on issues above and beyond the psychiatric diagnosis. Use of the multiaxial system requires that information be noted on each of five different axes, each axis devoted to a different aspect of the evaluation process. Axes I, II, and III are the diagnostic axes and divide up the diagnostic pie into three separate domains. Axis IV is for “clinical syndromes and disorders,” an admittedly confusing name since Axis II and Axis III are also diagnostic axes. The most accurate name for Axis I is “diagnoses not coded on Axis II and Axis III” since Axis II and Axis III were carved out of Axis I specifically to draw attention to certain disorders that clinicians were more likely to overlook.

That said, Axis II is designated for coding Personality Disorders and Mental Retardation. There have been many recent criticisms of the coding of Personality Disorders on Axis II. Critics correctly point out that there is no firm conceptual basis for this division. Although disorders on Axis II tend to be lifelong and pervasive, a number of disorders on Axis I (e.g., Schizophrenia, Autistic Disorder, Dysthymic Disorder) fit this description as well. Others have made the incorrect assumption that categories on Axis II are unresponsive to medication treatment, which is at odds with more recent evidence that medications are often helpful in the treatment of personality disorders. The fact is that the Axis I/Axis II division was made on strictly pragmatic grounds. It was introduced in DSM-III as a way of drawing attention to a set of disorders that were thought not to be given adequate attention by mental health professionals. First introduced in DSM-III, Axis II was designed to draw attention to certain disorders that were thought to be overshadowed in the face of the more florid Axis I presentations. In DSM-III, Axis II was reserved for personality disorders in adults and specific developmental disorders in children. In DSM-III-R, the developmental disorders (i.e., mental retardation, pervasive developmental disorders, specific developmental disorders) were coded on Axis II along with the personality disorders. In DSM-IV, Axis II was modified once again so that only personality disorders and mental retardation remain on Axis II. Certain the placement of personality disorders on a separate axis has increased both their clinical visibility and their importance as a subject for research studies. Whether the Axis I/Axis II division has finally outlived its usefulness remains a topic of heated debate, and will be revisited during the DSM-V deliberations.

Axis III, like Axis II, is intended to encourage clinicians to pay special attention to conditions that they tend to overlook; in this case, clinically relevant general medical conditions. The concept of “clinically relevant” is intended to be broad. For example, it would be appropriate to list hypertension on Axis III even if its only relationship to an Axis I disorder is its impact on the options for the choice of antidepressant medication.

Mental disorders differentially impact on individual’s level of functioning. For example, one patient with Schizophrenia may function quite well, being able to live in the community, marry and have a family, and maintain a steady job whereas another patient with Schizophrenia may function quite poorly, requiring chronic institutionalization. Since both of these patients have symptoms that meet the diagnostic criteria for Schizophrenia, their important differences in functioning is not captured by the clinical diagnosis alone. Some of the differences in functioning may be due to different symptom profiles or symptom severities. Other differences may be related to resilience factors or different levels of psychosocial support. Whatever the reason, the DSM-IV multiaxial system provides the clinician with the ability to indicate the patient’s overall level of functioning on Axis V, using the Global Assessment of Functioning (GAF) Scale (Figure 40–2). This GAF scale has been criticized because it is not actually a “pure” measure of an individual’s ability to function, since it incorporates symptom severity into the scale (e.g., level 41–50 is for “serious symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) or any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job)”). For this reason, the DSM-IV includes a scale (the Social and Occupational Functioning Scale (SOFAS)) that relies exclusively

---

**DSM-IV Classification and Diagnostic Codes**

The “DSM-IV Classification of Mental Disorders” refers to the comprehensive listing of the official diagnostic codes, categories, subtypes, and specifiers (see Figure 40–3). It is divided into various “diagnostic classes” which group disorders together based on common presenting symptoms (e.g., Mood Disorders, Anxiety Disorders), typical age-at-onset (e.g., Disorders Usually First Diagnosed in Infancy, Childhood, and Adolescence), and etiology (e.g., Substance-Related Disorders, Mental Disorders Due to a General Medical Condition).

The diagnostic codes listed in the DSM-IV are derived from the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM), the official coding system for reporting morbidity and mortality in the US. That is the reason why the codes go from 290.00
DSM-IV-TR CLASSIFICATION

NOS = Not Otherwise Specified.

An x appearing in a diagnostic code indicates that a specific code number is required.

An ellipsis (...) is used in the names of certain disorders to indicate that the name of a specific mental disorder or general medical condition should be inserted when recording the name (e.g., 293.0 Delirium Due to Hypothyroidism).

If criteria are currently met, one of the following severity specifiers may be noted after the diagnosis:
- Mild
- Moderate
- Severe

If criteria are no longer met, one of the following specifiers may be noted:
- In Partial Remission
- In Full Remission
- Prior History

Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence

MENTAL RETARDATION

Note: These are coded on Axis II.

317 Mild Mental Retardation
318.0 Moderate Mental Retardation
318.1 Severe Mental Retardation
318.2 Profound Mental Retardation
319 Mental Retardation, Severity Unspecified

LEARNING DISORDERS

Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence

The classification begins with Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence. The provision of a separate section for so-called childhood disorders is for convenience only. Although most individuals with these disorders present for clinical attention during childhood or adolescence, it is not uncommon for some of these conditions to be diagnosed for the first time in adulthood (e.g., Attention-deficit/Hyperactivity Disorder). Moreover, many disorders included in other sections of the DSM-IV have an onset during childhood (e.g., Major Depressive Disorder). Thus, a clinician evaluating a child or adolescent should not only focus on those disorders listed in this section but also consider disorders from throughout the DSM-IV. Similarly, when evaluating an adult, the clinician should also consider the disorders in this section since many of them persist into adulthood (e.g., stuttering, learning disorders, tic disorders).

The first set of disorders included in this diagnostic class (Mental Retardation, Learning Disorders and Motor Skills Disorders, and Communication Disorders) are covered in detail in Chapters 48, Chapter 49, and Chapter 50, respectively in this book. While these are not strictly speaking regarded as mental disorders, they are included in the DSM-IV to facilitate differential diagnosis and to increase recognition of these conditions among mental health professionals. Autism and Other Pervasive Developmental Disorders are discussed in Chapter 51 of this book and are characterized by gross qualitative impairment in social relatedness, in language, and in repertoire of interests and activities. Disorders covered include Autistic Disorder, Asperger’s Disorder, Rett’s Disorder, and Childhood Disintegrative Disorder. Attention-deficit/Hyperactivity Disorder and Other Disruptive Behavior Disorders (Chapter 52) are grouped together because they are all characterized (at least in their childhood presentations) by disruptive behavior. Chapter 53 on Feeding Disorders includes the DSM-IV categories of Pica, Rumination Disorder, and Feeding Disorder of Infancy and Early Childhood (also known as “failure to thrive”). Tic Disorders (Chapter 54), Elimination and Childhood Anxiety Disorders (Chapter 55) and Stereotyped
Movement Disorder and Reactive Attachment Disorder (Chapter 56) conclude the childhood section.

**Delirium, Dementia, Amnestic Disorder, and Other Cognitive Disorders**

In DSM-III-R, delirium, dementia, amnestic disorder, and other cognitive disorders were included in a section called “organic mental disorders,” which contained disorders that were due to either a general medical condition or substance use. In DSM-IV, the term organic was eliminated because of the implication that disorders not included in that section (e.g., schizophrenia, bipolar disorder) do not have an organic component (Spitzer et al. 1992). In fact, virtually all mental disorders have both psychological and biological components, and to designate some disorders as organic and the remaining disorders as nonorganic reflected a reductionistic mind-body dualism that is at odds with our understanding of the multifactorial nature of the etiological underpinnings of disorders.

DM-IV replaced each unitary organic mental disorder (e.g., organic mood disorder) with its two component parts (e.g., mood disorder due to a general medical condition and substance-induced mood disorder). Because of their central roles in the differential diagnosis of cognitive impairment, delirium, dementia, and amnestic disorder are contained within the same diagnostic class in DSM-IV and are discussed in Chapter 57 of this book.

Whereas both delirium and dementia are characterized by multiple cognitive impairments, delirium is distinguished by the presence of clouding of consciousness, which is manifested by an inability to appropriately maintain or shift attention. DSM-IV includes three types of delirium: delirium due to a general medical condition, substance-induced delirium, and delirium due to multiple etiologies.

Dementia is characterized by clinically significant cognitive impairment in memory that is accompanied by impairment in one or more other areas of cognitive functioning (e.g., language, executive functioning). DSM-IV includes several types of dementia based on etiology, including dementia of the Alzheimer’s type, vascular dementia, a variety of dementias due to general medical and neurologic conditions (e.g., human immunodeficiency virus infection, Parkinson’s disease), substance-induced persisting dementia, and dementia due to multiple etiologies.

In contrast to dementia, amnestic disorder is characterized by clinically significant memory impairment occurring in the absence of other significant impairments in cognitive functioning. DSM-IV includes amnestic disorder due to a general medical condition and substance-induced persisting amnestic disease.

**Mental Disorders due to a General Medical Condition Not Elsewhere Classified**

This diagnostic class includes all of the specific mental disorders due to a general medical condition, and is discussed in Chapter 58 of this book. In DSM-IV, most of the mental disorders due to a general medical condition have been distributed throughout the various diagnostic classes alongside their “nonorganic” counterparts in the classification. For example, mood disorder due to a general medical condition and substance-induced mood disorder are included in the mood disorders section of DSM-IV.

Two specific types of mental disorder due to a general medical condition (i.e., Catatonic Disorder due to a General Medical Condition and Personality Change due to a General Medical Condition) are physically included in this diagnostic class.

**Substance-Related Disorders**

The term substance in DSM-IV has a broader meaning than merely a drug of abuse. It also includes medication side effects and the consequences of toxin exposure. Two types of substance-related disorders are included in DSM-IV: substance use disorders (dependence and abuse), which describe the maladaptive nature of the pattern of substance use; and substance-induced disorders, which cover psychopathological processes caused by the direct effects of substances on the central nervous system. Criteria sets for Substance Dependence, Substance Abuse, Substance Intoxication, and Substance Withdrawal that apply across all drug classes are included before the substance-specific sections of DSM-IV. A discussion of these so-called “generic” criteria is covered in Chapter 59 of this book. Detailed discussions of each of the DSM-IV drug classes is covered in the subsequent chapters of this book as follows: Alcohol-Related Disorders in Chapter 60, Caffeine-Related Disorders in Chapter 61, Cannabis-Related Disorders in Chapter 62, Cocaine-Related Disorders in Chapter 63, Phencyclidine-Related Disorders in Chapter 64, Hallucinogen-Related Disorders (including MDMA) in Chapter 65, Inhalant-Related Disorders in Chapter 66, Nicotine-Related Disorders in Chapter 67, Opioid-Related Disorders in Chapter 68, and Sedative, Hypnotic, or Anxiolytic-Related Disorders in Chapter 69.

**Schizophrenia and Other Psychotic Disorders**

The title of this diagnostic class is potentially misleading for two reasons: (1) there are other disorders that have psychotic features there are not included in this diagnostic class (e.g., Mood Disorders with Psychotic Features, delirium) and (2) it may incorrectly imply that the other psychotic disorders included in this section are related in some way to Schizophrenia (which is only true for Schizophreniform Disorder and possibly Schizoaffective Disorder). Instead, what ties together all of the disorders in this diagnostic class is the presence of prominent psychotic symptoms. Included here Schizophrenia, Schizophreniform Disorder, Schizoaffective Disorder, Delusional Disorder, Shared Psychotic Disorder, and Brief Psychotic Disorder, each of which is discussed in this book in varying detail in Chapter 70.

It should be noted that the definition of the term “psychosis” has been used in different ways historically and is not even used consistently across the various categories in the DSM-IV. The most restrictive definition of psychosis (used in Substance-Induced Psychotic Disorder) requires a break in reality testing such that the person has delusions or hallucinations with no insight in the fact that the delusions or hallucinations are caused by taking drugs. A somewhat less restrictive definition of psychosis (not used in DSM-IV but advocated by some members of the DSM-IV Psychotic Disorders Workgroup as more appropriate for Substance-induced psychosis) includes hallucinations or delusions even if the person has insight into their origin.
(e.g., it would include an individual who was hallucinating after taking PCP even if he were aware that the hallucinations were due to the PCP). A much broader definition of psychosis (utilized in the definition of Schizophrenia, Schizophréniform, and Brief Psychotic Disorder) goes beyond delusions and hallucinations to include grossly disorganized speech and catatonic or grossly disorganized behavior as evidence for psychosis. Finally, the term psychosis was in the past used the most broadly to refer to any condition that caused serious functional impairment (e.g., “affective psychosis” is used in ICD-9 to refer to major mood disorders). This definition is not used at all in DSM-IV.

Mood Disorders
This diagnostic class includes disorders in which the predominant disturbance is in the individual’s mood. Although the term “mood” is broadly defined to include depression, euphoria, anger, and anxiety, the DSM-IV generally restricts mood disturbances to depressed, elevated, or irritable mood.

The mood disorders section begins with the criteria for mood episodes (major depressive episode, manic episode, hypomanic episode, mixed episode), which are the building blocks for the episodic mood disorders. The codable mood disorders come next and are divided in the depressive disorders (i.e., major depressive disorder and dysthymic disorder, described in this book in Chapter 71) and the bipolar disorders (i.e., bipolar I disorder, bipolar II disorder, and cyclothymic disorder, described in Chapter 72). Finally, the many specifiers that provide important treatment-relevant information close this section. Several so-called “subthreshold mood disorders” (i.e., they are characterized by depression but fall short of meeting the diagnostic criteria for either major depressive disorder or dysthymic disorder) are included in DSM-IV appendix B, for Criteria Sets and Axes Provided for Further Study. These include minor depressive disorder, brief recurrent depressive disorder, mixed anxiety depressive disorder, post-psychotic depressive disorder of schizophrenia (all briefly described in Chapter 71), and premenstrual dysphoric disorder (described in detail in Chapter 73).

Anxiety Disorders
The common element joining these disparate categories together is the fact the anxiety is a prominent part of their clinical presentation. This grouping has been criticized because of evidence suggesting that at least some of the disorders are likely to be etiologically distinct from the others. Most particularly, obsessive-compulsive disorder and posttraumatic stress disorder seem to share little in common with the other anxiety disorders. In fact, a separate diagnostic class for Stress-Related Disorders (that would also include Adjustment Disorders and perhaps Dissociative Disorders) and for Obsessive-Compulsive Spectrum Disorders (which might also include trichotillomania, tic disorders, hypochondriasis, body dysmorphic disorder and other disorders characterized by compulsive behavior) have been proposed.

Detailed discussions of the various anxiety disorders are covered in several chapters in this section of this book: Panic Disorder With and Without Agoraphobia in Chapter 74, Social and Specific Phobias in Chapter 75, Obsessive–Compulsive Disorder in Chapter 76, Posttraumatic Stress Disorder and Acute Stress Disorder in Chapter 77, and Generalized Anxiety Disorder in Chapter 78.

Somatoform Disorders
This diagnostic class includes disorders in which the defining feature is a physical complaint or bodily concern that is not better accounted for by a general medical condition or another mental disorder. These disorders (which are discussed in this book in detail in Chapter 79) can be divided into three groups based on the focus of the individual’s concerns: (1) focus on the physical symptoms themselves (Somatization Disorder, Undifferentiated Somatoform Disorder, Pain Disorder, and Conversion Disorder), (2) focus on the belief that one has a serious physical illness (Hypochondriasis), and (3) focus on the belief that one has a defect in physical appearance (Body Dysmorphic Disorder).

Factitious Disorders
This diagnostic class contains only one disorder: Factitious Disorder, which describes presentations in which the individual intentionally produces or feigns physical or psychological symptom in order to fulfill a psychological need to assume the sick role. It is discussed in detail in Chapter 80 of this book. Factitious Disorder should always be distinguished from malingering, in which the individual is also pretending to have physical or psychological symptoms. The difference is that in malingering, the person’s motivation is to achieve some external gain (e.g., disability benefits, lessening of criminal responsibility, shelter for the night). For this reason, unlike Factitious Disorder, malingering is not considered a mental disorder.

Dissociative Disorders
The common element to this group of disorders is the symptom of dissociation, which is defined as a disruption in the usually integrated functions of consciousness, memory, identity, and perception. Four specific disorders are included (Dissociative Amnesia, Dissociative Fugue, Dissociative Identity Disorder, and Depersonalization Disorder) and are discussed in this book in detail in Chapter 81.

Sexual and Gender Identity Disorders
This diagnostic class contains three relatively disparate types of disorders, linked together only by virtual of their involvement in human sexuality. Sexual Dysfunctions refer to disturbances in sexual desire or functioning, Paraphilias refer to unusual sexual preferences that interfere with functioning (or in the case of preferences that involve harm to others like Pedophilia, merely acting on those preferences), and Gender Identity Disorder refers to a serious conflict between one’s internal identity of maleness or femaleness (gender identity) and one’s anatomical sexual characteristics. These categories are discussed in this book in detail in Chapter 82.

Eating Disorders
Although the name of this diagnostic class focuses on the fact that this disorders in this section are characterized by abnormal eating behavior (refusal to maintain adequate body weight in the case of Anorexia Nervosa and discrete episodes of uncontrolled eating of excessively large amounts of food in the case of Bulimia Nervosa), of near
equal importance is the individual’s pathological overemphasis on body image. A third category, which is being actively researched but has not been officially added to the DSM-IV is binge eating disorder (i.e., it is included in the appendix of criteria sets and axes provided for further study). Like Bulimia Nervosa, individuals with binge eating disorder have frequent episodes of binge eating. However, unlike Bulimia Nervosa, these individuals do not do anything significant to counteract the effects of their binge eating (i.e., they do not purge, use laxatives or diet pills or excessively exercise). All three disorders are described in this book in Chapter 83.

Sleep Disorders
Sleep disorders are grouped into four sections on the basis of presumed etiology (primary, related to another mental disorder, due to a general medical condition, and substance induced). Two types of primary sleep disorders are included in DSM-IV: dyssomnias (problems in regulation of amount and quality of sleep) and parasomnias (events that occur during sleep). The dyssomnias include Primary insomnia, Primary hypersomnia, Circadian rhythm sleep disorder, Narcolepsy, and Breathing-related sleep disorder, whereas the parasomnias include Nightmare disorder, Sleep terror disorder, and Sleepwalking disorder. Sleep Disorders are described in detail in this book in Chapter 84.

Impulse-Control Disorders Not Elsewhere Classified
As is suggested by the title of this diagnostic grouping, no one diagnostic class in DSM-IV comprehensively includes all of the impulse control disorders. A number of disorders characterized by impulse control problems are classified elsewhere (e.g., Conduct Disorder, Attention-deficit/Hyperactivity Disorder, Oppositional-defiant Disorder, Delirium, Dementia, Substance-Related Disorders, Schizophrenia and Other Psychotic Disorders, Mood Disorders, Antisocial and Borderline Personality Disorders). What ties together the disorders in this class is that they present with clinically significant impulsive behavior and that they are not better accounted for by one of the mental disorders included in other parts of DSM-IV. Five such disorders are included here: Intermittent Explosive Disorder, Pathological gambling, Pyromania, Kleptomania, and Trichotillomania. These are discussed in this book in Chapter 85.

Adjustment Disorders
All DSM-IV categories (except Not Otherwise Specified (NOS) categories) take priority over adjustment disorder. This category is intended to apply to maladaptive reactions to psychosocial stressors that do not meet the criteria for any specific DSM-IV disorder. These are discussed in Chapter 86 of this book.

Personality Disorders
This diagnostic class is for personality patterns that significantly deviate from the expectations of the person’s culture, are pervasive, and lead to significant impairment or distress. Ten specific personality disorders are included in DSM-IV: Paranoid personality disorder (pervasive distrust and suspiciousness of others), Schizoid personality disorder (detachment from social relationships and a restricted expression of emotions), Schizotypal personality disorder (acute discomfort with close relationships, perceptual distortions, and eccentricities of behavior), Antisocial personality disorder (disregard for the rights of others), Borderline personality disorder (instability of personal relationships, instability of self-image, and marked impulsivity), Histrionic personality disorder (extensive emotionality and attention seeking), Narcissistic personality disorder (grandiosity, need for admiration, and lack of empathy), Avoidant personality disorder (social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation), Dependent personality disorder (excessive need to be taken care of), and Obsessive–compulsive personality disorder (preoccupation with orderliness, perfectionism, and mental and personal control at the expense of flexibility, openness, and efficiency). These are discussed in detail in this book in Chapter 87.

Other Conditions That May Be a Focus of Clinical Attention
This section of DSM-IV is for problems that are not mental disorders but that may be a focus of attention or treatment by a mental health professional. Psychological factors affecting medical condition is intended to allow the psychiatrist to note the presence of psychological factors (e.g., Axis I or II disorder) that are adversely affecting the course of a general medical condition, including factors that interfere with treatment and factors that constitute health risks to the individual. (This condition is described in Chapter 88 of this book). Six specific medication-induced movement disorders (discussed in this book in Chapter 89) are also included because of their importance in treatment and differential diagnosis; five are related to neuroleptic administration, and one (medication-induced postural tremor) is most often associated with the use of lithium carbonate. Although these are best considered medical conditions, by DSM-IV convention they are coded on Axis I.

Relational problems (discussed in this book in Chapter 90) include parent-child, partner, and sibling relational problems. Relational problems related to a mental disorder or general medical condition applies to situations in which one member of the relational unit has a mental disorder or a general medical condition. In such situations, the relational dynamics can negatively affect the individual's condition or vice versa (or both). Problems related to abuse or neglect (physical abuse, sexual abuse, and child neglect) have been introduced into DSM-IV because of the clinical and public health significance of these conditions.

Appendix Categories

DSM-IV aims to be on the trailing edge rather than the cutting edge of research (Pincus et al. 1992). New categories were considered for inclusion only if there was a substantial research literature behind them. Although there were proposals for more than 100 new categories to be introduced into DSM-IV, only a handful of new categories were added. Text and criteria for another 17 proposed categories have been included in a DSM-IV appendix, Criteria Sets and Axes Provided for Further Study (Table 40–4). These criteria sets have been included to provide a common language for researchers and psychiatrists who are interested in further investigating their potential utility and validity.

Infancy and early childhood is characterized by dynamic relationships between the different dimensions of human development, including emotional, social, language, cognitive, regulatory–sensory processing, and motor capacities. No classification system currently exists that describes challenges in each of these areas of functioning and the relationships between them. A dynamic, developmental, and multiaxial approach that includes all the relevant dimensions of human development is especially vital during these formative years when not only are the brain and mind growing more rapidly, than they ever will again, but they are literally forming the relationships between its different components. Attending to these interconnected components is essential in classifying disorders as the basis for meaningful intervention planning and research.

The new Interdisciplinary Council on Developmental and Learning Disorders Diagnostic Manual for Infants and young Children (ICDL-DMIC) utilizes a comprehensive approach which includes interactive, neurodevelopmental, regulatory-sensory processing, language, and learning disorders (Interdisciplinary Council on Developmental and Learning Disorders 2005). It emphasizes the multiple relationships between different areas of development and can identify those infants and young children who present with a specific type of problem but often have challenges in other areas of functioning. For example, a preschooler with an impulse control problem will often have challenges in terms of caregiver/child-interaction patterns and different aspects of sensory processing, language, and cognition. Similarly, children with language problems may also often evidence contributions from challenges in motor planning and sequencing and other aspects of sensory processing. Challenges in any area can derail healthy emotional development and relationships.

The ICDL-DMIC introduces the concept of the developmental pathways which guides understanding of why particular symptoms develop related to the way the child reacts to and comprehends different sensations and plans actions (an expression of his or her biological patterns), the ways in which the caregiving environment interacts with these individual differences (within the normative range of individual differences, but not at the level of a disorder), and the levels or stages of emotional and intellectual organization that are negotiated through these interactions. These interrelated elements constitute the Developmental, Individual Difference, Relationship-based (DIR) model (Greenspan and Wieder 1997). ICDL-DMIC was conceptualized over a thirty year period, beginning with the research conducted at the Clinical Infant Development program (by The National Institute of Mental Health (NIMH) which is a part of the National Institutes of Health (NIH); a component of the U.S. Department of Health and Human Services) when leading infant researchers (Reginald Lourie, Selma Fraiberg, T. Berry Brazelton, Julius Richmond, Ed Ziegler, Katherine Barnard, and many others) met to formulate the critical factors essential for infant mental health. This led to the Task Force at Zero to Three (National Center for Clinical Infant Programs 1994), The National Center for Infants, Toddlers, and Families, which developed the first Diagnostic Classification (DC 0–3), chaired by Greenspan and Wieder, and then to the Interdisciplinary Council on Developmental and Learning Disorders.
The need for a developmentally-based classification system
Multidimensional Development Approach
The Need for a Comprehensive
An Interdisciplinary Approach to Classification
This classification system integrates all components of development and functioning which have been traditionally addressed by different disciplines. It is designed for professionals credentialed to do diagnoses. It can also be used by all disciplines as a roadmap to understanding the interactions between the different components of the child's development, their family, and environment in order to guide assessments and interventions. It augments other existing diagnostic systems such as ICD-10, DSM IV-TR, and DC-0-3R. For the reason that the ICDL-DMIC is an interdisciplinary tool that supports the integration of knowledge from different disciplines, it will, for example, guide the mental health professional to integrate what has been learned about development, regulatory-sensory processing, language, visuospatial, and learning capacities into their mental health expertise. Similarly, the ICDL-DMIC will help pediatricians, occupational, physical, and speech and language therapists, educators, and professionals from other disciplines in their ability to integrate their understanding of the impact of emotional development, interactive disorders, and family and environmental factors on adequate, constricted or disordered functioning.

The Need for a Comprehensive Multidimensional Developmental Approach
The need for a developmentally-based classification system in infant and early childhood mental health that includes neurodevelopmental, regulatory-sensory processing, language, and learning disorders is based on a number of challenges that now face clinicians and researchers working with infants, young children, and their families.

Symptom-based diagnostic approaches which rely on lists of categorical symptoms that are readily observable are used in the belief that they facilitate reliable judgments. The symptom-based approach, however, has not demonstrated the clinical validity, including predicting clinical course or informing clinical practice, to the degree hoped for. For many diagnoses, the reliability among practicing clinicians making the diagnosis has also been disappointing (Burmua 2005).

The most significant weakness in the symptom-based approach has been the confusion it has brought regarding the boundaries between disorders and the usefulness of the diagnostic categories for planning optimal treatment approaches. The degree to which many conditions evidence comorbidity with other conditions illustrates the problem with a symptom-based approach that is not sufficiently grounded in an understanding of etiological factors or the developmental pathways leading to disordered functioning. For example, often the symptom-based approaches have designated diagnostic categories, including boundaries between conditions, based simply on the consensus of experts, including decisions about how many of the symptoms are necessary for the diagnosis (e.g., three out of five, rather than two out of five). Yet there are insufficient studies documenting what it means if the patient meets only two out of five (i.e., there is no data supporting a clear line between having two items versus having three items of the criteria set). Therefore, most evidence points to a dimensional approach where symptoms or disorders may be expressed in varying degrees (i.e., shades of gray) rather than clear “you have it or you don’t.” Many difficulties exist in terms of degrees of challenge, rather than with clear boundaries.

The length of time symptoms need to be manifested for a disorder to be diagnosed is another example of over-specificity, that is symptoms must be present for at least X number of weeks. Again, there is insufficient data on the implications of a patient evidencing it two days less than the indicated two weeks. Most importantly, studies of prognosis and predictive validity are hampered by not controlling for the appropriateness of the treatment program the patient is receiving. For example, most children with autism are believed to continue to evidence the symptoms of the disorder five to eight years in the future. But how many of these children were in inappropriate or inadequate treatment programs? Prognosis with an optimal treatment program is not yet definitively known, due to the lack of comparative clinical trials of the most promising approaches and lack of a sufficient number of long-term naturalistic studies (Committee on Educational Interventions for Children with Autism for National Research Council 2001).

Reliability studies are also fraught with problems. Criteria that are easy to agree on are not necessarily the criteria that are meaningful for clinical planning or research on etiological factors and developmental pathways. In general, there is a healthy tension between the goal of capturing the true complexity of multifaceted clinical phenomena and developing criteria that can be reliably judged and employed in research. It is vital to embrace this healthy tension and pursue a stepwise approach where complexity and clinical usefulness is a cornerstone for efforts at increasingly systematic operational definitions and research on reliability and clinical validity. A scientifically based system is one that recognizes a stepwise progression that begins with accurate recognition and description of complex clinical phenomena and builds gradually through a series of steps toward empirical validation. Recognizing this will enable us to climb the steps of science without skipping over any important ones. If we sacrifice meaningful categorization for quick reliability, we will wind up with a system fraught with problems. Diagnostic agreement does not imply clinical validity. Therefore, the next goal is to improve our conceptual framework by deepening and broadening it. At present, it is important to acknowledge that we do not yet have an...
empirically validated diagnostic system for mental health, developmental, and learning disorders of infancy and early childhood. We do have emerging data and a great deal of clinical experience. Therefore, an accurate statement of the field is that it is currently operating on expert consensus with supportive, but incomplete data.

**Multidimensional Classification Based on the DIR Model**

As indicated, dimensional approaches tend to be based on an implicit understanding that most mental health and developmental disorders are based on complex dynamic, developmental processes. We have formulated a developmental, biopsychosocial model to describe the processes that contribute to mental health, development, regulatory-sensory processing, language, and learning disorders in infancy and early childhood—DIR approach. The DIR approach focuses on Developmental capacities (D)—the level of emotional, social, and intellectual functioning (technically called functional emotional developmental capacities). It also focuses on biologically based Individual processing differences (I) in the way an infant or young child reacts to and comprehends different sensations, such as auditory, visuospatial, or tactile, as well as the way in which the child plans, sequences, and executes actions. It also focuses on the Relationships (R), including child/caregiver/family and other relationship patterns.

**Unique Features of the ICDL-DMIC Multiaxial System**

Comprehensiveness and systematization guided the ICDL work groups in creating this manual. Only a diagnostic system that describes the full complexity of disordered functioning and characterizes different subtypes can provide a basis for basic research on underlying etiologies and developmental pathways. A number of unique features operationalize this perspective. For example, each of the primary disorders classified under the heading “Interactive Disorders” is described in terms of its clinical phenomena, presenting symptoms, developmental pathways, and therapeutic implications. In addition, each disorder is described along a number of axes, which attempts to capture and emphasize an important component of, and/or contributor to, the disorder. These include the infant’s or young child’s level of emotional and social functioning, child-caregiver and family interaction patterns, motor planning and processing differences (regulatory sensory processing profile), language functioning, visuospatial capacities, and unique stressors that may be affecting the child and his or her family. Each Axis is briefly described below and summarized in Figure 41-1.
**Axis I: Primary Diagnosis**
The broad diagnostic category—Interactive Disorder, RSPD, Neurodevelopmental Disorder of Relating and Communicating, Language Disorder, and/or Learning Challenges—and the specific type of disorder within the category.

**Axis II: Functional Emotional Developmental Capacities**
The relative mastery of each of the functional emotional developmental capacities, including shared attention and regulation, engagement and relating, two-way intentional, affective signaling and communication, long chains of coregulated emotional signaling and shared social problem solving, creating symbols or ideas, building bridges between ideas-logical thinking.

**Axis III: Regulatory-Sensory Processing Capacities**
The regulatory-sensory processing capacities, in terms of self-regulation, sensory modulation, sensory discrimination, and sensory-based motor abilities, including postural control and motor planning.

**Axis IV: Language Capacities**
Includes gestural and verbal communication (comprehension and production) at each developmental level.

**Axis V: Visuospatial Capacities**
The progressive development of visuospatial aspects of body awareness and sense thinking, location of the body in space, relation of objects to the self and other objects and people, conservation of space, visual logical thinking, and representational thought.

**Axis VI: Child-Caregiver and Family Patterns**
Characteristics of infant or child-caregiver interaction patterns and family or environmental patterns.

**Axis VII: Stress**
Stressors related to situations, conditions or events in the family’s or child’s life which can impact the child’s emotional functioning and development when appropriate protective factors or adequate resiliency is not evident.

**Axis VIII: Other Medical and Neurological Diagnoses**

**Selecting a Primary Diagnosis**
Most infant and early childhood disorders are characterized by multiple elements or dimensions, for example, interactive and family patterns, and regulatory—sensory processing patterns. These disorders include anxiety and mood disorders, disruptive behavior, elective mutism, as well as sleep, eating, and elimination disorders. A multiaxial approach will allow a systematic description of each of the contributing elements. Before concluding on a primary diagnosis, all the axes must be fully evaluated in order to determine the various dimensions contributing to the presenting problems. Once all this information is considered, clinical reasoning will guide the experienced clinician in selecting the predominant pattern and identifying how the developmental pathway contributes to the symptom choice.

The decision process would first consider **the most comprehensive disorder** where multiple elements of development are derailed. For example, NDRC includes RSPD, Language Disorder, and emotional constrictions. When relating and communicating are not significantly derailed then the RSPD are considered next to see if the presenting behavioral patterns are coupled with motor and/or regulatory—sensory processing challenges. When a regulatory—sensory processing contribution is significant, it will take precedence over the interactive elements in the designation of the primary diagnosis. If interactive challenges dominate, it becomes the primary disorder.

With Interactive Disorders there is so much overlap in symptoms, the clinician must consider when the symptom is part of a broader disorder such as anxiety, mood or disruptive behavior, and when it is itself the primary disorder. For example, if a child with Anxiety Disorder also has sleep problems, but the sleep problem is intermittent or a temporary disruption of a developmental capacity already mastered, along with possible other disruptions in eating or toileting, then an additional diagnosis would not be necessary. However, if the sleep problem is very intense or of longer duration, and also meets the description of the primary disorder, then it could be considered a second primary diagnosis. Similarly, if a child manifests disruptive or oppositional behavior, Anxiety Disorder or Disruptive Behavior Problem could be considered and the differentiating consideration would be whether the child has a pattern of impulse control problems in various situations or emotional states. If not, then Anxiety Disorder may be the only primary diagnosis selected. More than one diagnosis is permitted under this system. In addition, as indicated earlier, we emphasize a Language Disorder or Learning Challenge can be used as a second primary diagnosis when a child evidences a significant difficulty in either of these areas of functioning. In other words, clinical reasoning must determine if the multiple symptoms are significant enough to constitute an additional diagnosis or are part of the primary problem.

**Clinical Thresholds for Diagnosis**
Deciding when a behavioral or emotional pattern constitutes a disorder rather than a disruption or variation within the normal range presents the clinician with a challenge. This can be especially difficult during the first five years when development is proceeding rapidly and has so much variation influenced by individual differences. It is also a challenge when so many of the same symptoms can relate to different disorders given the limited number of symptoms in the infant’s and young child’s repertoire.

Since we are currently operating on expert consensus with supportive, but incomplete, data, this classification system utilizes functional or operational considerations to make the clinical judgment of whether the presenting problems cross the clinical threshold to be considered a disorder. The following hierarchy should be considered:

- Is the child functioning within his or her age-expected functional developmental capacities? What is the range of the child’s comprehension and expression of emotions with gestures and/or words or play, in comparison to age expectations? See Axis II (Functional Emotional...
Developmental Capacities) as well as the other clinical assessments.

- How well is the child functioning within the family structure on a daily basis including routines of sleep, meals, play, relating to family, caregivers and sibling interactions? Is the environment stable? Is the child stable?
- Is the child adapting to daycare or preschool adequately and able to enjoy these environments and learning experiences?
- Is the child participating in expected social interactions, developing friendships, and able to play with peers?
- What are the child's emerging attitudes and feelings toward himself or herself and others (e.g., angry, depressed, suspicious, etc.) in comparison to what is expected for his or her age (e.g., some degree of negativism is expected during the preschool years)?

The child may present significant challenges in any one of these areas which may be sufficient to warrant a diagnosis such as difficulties in relating and communicating. In some cases, more than one area may be involved but the problem may not be spilling over significantly to preschool or peer play, such as a disorder of emotional range and stability where constrictions are significant and family interactions cannot support healthier emotional development. Sometimes, the threshold is not crossed until the preschool brings the problem to the attention of the family—the problem may not be perceived or evidenced at home, yet is significantly impeding the child's adaptation at school. The greater the number of areas of functioning that are involved, the more likely a diagnosis is indicated.

Furthermore, in addition to the detailed descriptions of the primary diagnosis (Axis I) to guide clinical judgment, Axes II through VII require a clinical formulation indicating the degree to which impairment is evident. The more severe the impairment or delay of the expected developmental capacities, the greater the evidence for the disorder(s). Clinical judgment relies on evaluating the functional or operating capacities and each of the dimensions in this multiaxial system to determine if the clinical threshold for a diagnosis has been crossed.

Even when the clinical threshold is not crossed, the diagnostic process and evaluation provides the parent with a better understanding of their child's profile of strengths and vulnerabilities and allow anticipatory guidance to better support the development of the child and family in the future.

**Axis I: Primary Diagnosis**

Interactive disorders are characterized by the way a child perceives and experiences his emotional world and/or by a particular maladaptive child-caregiver interaction pattern (Greenspan 1992). The caregiver's personality, fantasies and intentions; the child's emerging organization of experience; and the way these come together through child-caregiver interactions are important components of the basis for understanding the nature of the difficulty and for devising an effective intervention plan. As with all infant and early childhood disorders, it is also important to consider the child's constitutional-maturational variations, and family and environmental factors (Axes VI and VII). Although each child has a unique regulatory–sensory processing profile, constitutional-maturational variations are not a major contributing factor in interactive disorders, as they are in the category of RSPD.

The evaluating clinician must also consider the interaction patterns characteristic of each of the six developmental levels and determine which patterns have been negotiated successfully and which are absent or constricted. These are captured in Axis II. Regardless of the symptom, the goal of treatment is not only to alleviate it, but also to facilitate the child's progress toward an age-appropriate developmental level and toward an age-appropriate degree of stability and range of thematic experience.

Symptoms that can reflect an interactive disorder include anxiety, fears, behavior control problems, and sleeping and eating problems. The same symptoms can be reflective of any number of diagnoses. This is understandable in light of the limited number of behaviors or limited expression of feelings infants and young children are capable of. This category also includes transient situational adjustment reactions, such as a child's response to his mother's return to work. It also includes certain reactions to trauma in which the response does not involve multiple aspects of development.

The abbreviated version of the primary disorder “101. Anxiety Disorder” illustrates the ICDL-DMIC approach to Axis I. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail regarding the other primary disorders in Axis I.

**101. Anxiety Disorder**

Infants and young children may evidence persistent levels of anxiety and fear which impede age-expected ranges in...
of emotions and functioning. In infants and very young preverbal children anxiety is of a more generalized nature, in which symptoms such as excessive fearfulness, tantrums, agitation, avoidance, panic reactions, and worries are in evidence on a persistent basis even when the child is not threatened by separation from a primary caregiver. In the older child anxiety can take the form of specific fears or verbalized worries, obsessions or preoccupations, excessive tantrums, distress and agitation, and avoidance or counterphobic behaviors. The child may talk about his or her fears but not respond to reassurances, or may have a freeze, fight or flight reaction and is clearly distressed and fearful and cannot carry on usual routines and activities without significant disruptions during the day or night. At all ages, hypervigilant behavior can be an indicator of an anxiety disorder, and has been observed even in very young infants (3 to 4 months of age). The child may appear frightened, overly reactive, and overly focused, as though there were imminent danger. Infants who are abused may show this reaction quite early in their development, although it can manifest itself at any time.

For any form of anxiety, consider the following potential sources. First, is the anxiety primarily related to a RSPD (see 200. RSPD) Second, is the anxiety primarily related to expected developmental transitions or tasks the child is having difficulty mastering? Third, is the anxiety primary related to infant-caregiver interactions? The primary source of the anxiety may not always be clear.

Interactive elements are evident in situations where the primary caregiver is not providing ongoing personal security and may be unable to alleviate the anxiety through such strategies as helping the child anticipate what might be causing the anxiety, problem solving conversations, practice in pretend play, preparing the child for what will occur; and soothing, and reassuring the child sufficiently if the anxiety increases. The caregiver may also be anxious and distressed and anticipate the child’s anxiety and feel ill equipped to help, or feel annoyed, or overly worried. He or she may also be bringing his or her own anxieties to the situation at hand, such as social inhibition, or a specific phobia such as fear of dogs, or over-identifying with the child who reminds him or her of similar childhood experiences. In either case, the interaction between the child and caregiver increases the anxiety and distress and makes it difficult to support the child.

The Developmental Pathway: A particular type of infant-caregiver interaction combined with a particular regulatory–sensory processing profile often results in the child evidencing excessive anxiety. Individuals prone to anxiety tend to be over-reactive to sensations like sound and touch and to experience and express affect intensely. The caregiver then overreacts to the child’s emotional communications. As a consequence, the child feels overwhelmed and dysregulated. The anxious child constantly feels overwhelmed and experiences dysphoric or unpleasant affects associated with being overwhelmed (as opposed to loss or rupture in the relationship as the depressed child might experience).

Therapeutic Implications: The child prone to anxiety require long chains of especially soothing, reciprocal emotional interactions; therapy needs to focus on use of affects as a symbolic signal to cope and not escalate or panic, on expectations that relationships will intrude or overwhelm. Along with verbal awareness of his affective and interactional patterns as well as symbolic elaboration in play and conversation, the anxiety-prone individual needs to experience new ways of engaging in interactive, affective exchanges and signaling.

RSPD, involving symptom patterns such as inattention, over-reactivity, and sensory seeking, and refer to those challenges where differences in the child’s constitutional and maturational variations, in terms of sensory over- or under-reactivity, visuospatial, auditory and language processing, or motor planning and sequencing difficulties are a primary contributor to the child’s challenges.

### 200. Regulatory-Sensory Processing Disorder (RSPD)²

#### Sensory Modulation Challenges (Type I)
- 201. Over-Responsive, Fearful, Anxious Pattern
- 202. Over-Responsive, Negative, an Stubborn Pattern
- 203. Under-Responsive, Self-Absorbed Pattern
  - 203.1 Self-Absorbed and Difficult to Engage Type
  - 203.2 Self-Absorbed and Creative Type
- 204. Active, Sensory Seeking Pattern

#### Sensory Discrimination Challenges (Type II) and Sensory-Based Motor Challenges (Type III)
- 205. Inattentive, Disorganized Pattern
- 205.1 With Sensory Discrimination Challenges
- 205.2 With Postural Control Challenges
- 205.3 With Dyspraxia
- 205.4 With Combinations of 205.1-205.3
- 206. Compromised School and/or Academic Performance Pattern
- 206.1 With Sensory Discrimination Challenges
- 206.2 With Postural Control Challenges
- 206.3 With Dyspraxia
- 206.4 With Combinations of 206.2-206.3

#### Contributing Sensory Discrimination and Sensory-Based Motor Challenges
- 207. Mixed Regulatory-Sensory Processing Patterns
  - 207.1 Attentional Problems
  - 207.2 Disruptive Behavioral Problems
  - 207.3 Sleep Problems
  - 207.4 Eating Problems
  - 207.5 Elimination Problems
  - 207.6 Elective Mutism
  - 207.7 Mood Dysregulation, including Bipolar Patterns
  - 207.8 Other Emotional and Behavioral Problems Related to Mixed Regulatory-Sensory Processing Difficulties
  - 207.9 Mixed Regulatory-Sensory Processing Difficulties where Behavioral or Emotional Problems Are Not Yet in Evidence

²Work Group members include: Lucy J. Miller, Ph.D., OTR, Marie Anzalone, Sc.D., OTR, Sharon A. Cermak, Ed.D., OTR/L, Shelly J. Lane, Ph.D., OTR, Beth Osten, M.S., OTR/L, Serena Wieder, Ph.D., Stanley I. Greenspan, M.D.
All children evidence their own unique regulatory—sensory processing patterns. These variations are important to consider when constructing a developmental profile for a specific infant or child and his or her family. RSPD, however, should be considered when the child’s motor and sensory differences are contributing to challenges that interfere with age-expectated emotional, social, language, cognitive (including attention), motor, or sensory functioning. RSPD gives rise to some of the same symptoms and behaviors as interactive disorders, including nightmares, withdrawal, aggressiveness, fearfulness and anxiety, sleeping and eating disturbances, and difficulty in peer relationships. However, RSPD involves clearly identifiable constitutional—maturational factors in the child.

The diagnosis of RSPD involves a distinct behavioral pattern and a sensory modulation, sensory—motor, sensory discrimination or attentional processing difficulty. When both a behavioral and a sensory pattern are not present, other diagnoses may be more appropriate. For example, an infant who is irritable and withdrawn after being abandoned may be evidencing an expectable type of relationship or attachment difficulty. An infant who is irritable and overly responsive to routine interpersonal experiences, in the absence of a clearly identified sensory, sensory—motor or processing difficulty, may have an anxiety or mood disorder. Sleep and eating difficulties, in the absence of identifiable sensory responsivity or sensory processing differences, are classified as disorders in their own right. Further evaluation is then needed to determine whether the cause is an interactive disorder or some other underlying problem that does not fall within our three broad categories. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Type I: Sensory Modulation Challenges
Sensory Modulation Challenges (such as over-responsivity, under-responsivity, and sensory-seeking) are characterized by an inability to grade the degree, intensity, and nature of responses to sensory input. Often the child’s responses do not fit the demands of the situation. The child therefore demonstrates difficulty achieving and maintaining an optimal range of performance and adapting to challenges in daily life.

Type II: Sensory Discrimination Challenges
Sensory Discrimination Challenges are problems discerning the characteristics of sensory stimuli. The result is a lessened capability to interpret or give meaning to the specific qualities of stimuli, to detect similarities and differences among stimuli, and to differentiate the temporal and/or spatial qualities of stimuli. Children can perceive that stimuli are present and can modulate their responses to the stimuli, but cannot tell precisely what or where the stimulus is. Children with this challenge have difficulty interpreting the spatial and temporal qualities of sensory input and, as such, cannot use time and space information or other specific characteristics of the sensory experience to guide performance.

Type III: Sensory-Based Motor Challenges (Postural Regulation Difficulties and Dypraxia)
Postural challenges refer to difficulty stabilizing the body during movement or at rest in order to meet the demands of the environment or of a given motor task. Postural problems are characterized by inappropriate muscle tension, hypo- or hypertonic muscle tone, inadequate control of movement, and/or inadequate muscle contraction to achieve movement against resistance. Postural difficulties frequently occur in the presence of vestibular, proprioceptive, and visual—motor problems, and include poor stability in the trunk, poor righting and equilibrium reactions, poor trunk rotation and/or poor ocular control.

Postural challenges can occur with or without a motor planning disorder, although it is often observed with dyspraxia, particularly in difficulty with bilateral integration activities (e.g., doing activities that require use of both sides of the body together such as riding a bike, pumping a swing, etc.) and with rhythmical activities (e.g., bouncing a ball, clapping on the beat). Dyspraxia is an impairment in the ability to plan, sequence and execute novel or unfamiliar actions. It is characterized by awkward and poorly coordinated motor performance, which can be observed in gross motor, fine motor and/or oral motor abilities. To be diagnosed with sensory-based dyspraxia, deficits must manifest in processing of sensory information in one or more of the following sensory domains: tactile, kinesthetic, proprioceptive, or vestibular. Visual—motor and visual spatial deficits usually accompany this difficulty also.

These children learn by trial and error, with decreased ability to generalize skills to other similar motor tasks. Execution of discrete motor skills (e.g., standing, walking, pincer grasp) may be adequate. However, the performance of complex tasks may be compromised, including tasks that require one or more of the following: significant sequencing, important timing aspects, rhythm of motor action, or subtle adaptation in the “moment of action.” All three patterns involve inattentive, disorganized behavioral patterns and school performance and academic problems. NDRC involve symptom patterns, such as self-absorption, perseveration, and dysfunctional communication and refers to developmental disorders, including autism spectrum disorders, where there are significant difficulties with the fundamental capacities to relate, communicate, and think.

300. Neurodevelopmental Disorders of Relating and Communicating (NDRC)
301. Type I - Early Symbolic, with Constrictions
302. Type II - Purposeful Problem Solving, with Constrictions
303. Type III - Intermittently Engaged and Purposeful
304. Type IV - Aimless and Unpurposeful
Other Neurodevelopmental Disorders (Including Genetic and Metabolic Syndromes)
Children Who Are Difficult to Classify

Since the description of multisystem developmental disorders in DC:0-3, a work group of the ICDL has developed the current classification of NDRC. The Work Group members include: Serena Wieder, Ph.D., Lois Black, Ph.D., Griffin Doyle, Ph.D., Barbara Dunbar, Ph.D., Barbara Kalmanson, Ph.D., Lori-Jean Pelouquin, Ph.D., Ricki Robinson, M.D., M.P.H., Ruby Salazar, LCSW, Rick Solomon, M.D., Rosemary White, OTR, Molly Romer Witten, Ph.D., and Stanley I. Greenspan, M.D.
These categories include the kinds of problems that are currently conceptualized in DSM-IV-TR, but not in a sufficiently developmental or comprehensive manner. NDRC often include regulatory–sensory processing difficulties. If, however, basic relating, communicating, and thinking are disrupted, the problems would be classified under this category. RSPD may also involve interactive difficulties. However, if constitutional-maturational variations are a significant contribution, the problems are classified in this category. Interactive Disorders may involve constitutional and maturational variations as well as infant-caregiver interactions. However, in Interactive Disorders, the constitutional-maturational variations are not in the “clinical” (i.e., disordered) range and the major contributor to the problems stems from the caregiver-child interaction and related family and environmental patterns.

The only exception to the principles stated above relates to disorders involving trauma. These are classified under Interactive Disorders. Reactions to trauma may involve regulatory–sensory processing changes, such as sensory over-responsiveness; responses to trauma may also often involve anxiety or depression. When a clear trauma can be identified and is clinically thought to be responsible for the symptoms, priority is given to the diagnosis of traumatic stress disorder.

Table 41–1 is a very brief overview of the types of NDRC and is provided as a summary to facilitate the use of this framework in a variety of clinical and research settings. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Language Disorders include challenges in communication in the context of a developmental framework that considers all components of language (e.g., gestures, motor, sensory, social, etc.). These can constitute a primary disorder when not part of another major disorder such as NDRC. Language capacities also have their own profile (see Axis IV) because of the significance of language in development, as well as its impact on overall development. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Learning challenges are included in this classification in order to identify the early pathways associated with later learning differences and challenges at school age. The goal is to optimize early interventions which may head off or ameliorate these challenges later. These include learning difficulties in reading and reading comprehension, math, and written expression, as well as organizational capacities (i.e., executive functioning). See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Axes II-VIII

In addition to the detailed descriptions of the primary diagnosis, evaluation of the functional or operating areas and Axes II-VIII determines if the clinical threshold for a diagnosis has been crossed. The more severe the impairment or delay of the expected developmental capacities, the greater the evidence for the disorder(s).

Below is a brief description outlining Axes II-VIII. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Axis II: Functional Emotional Developmental Capacities

Axis II identifies six basic functional emotional developmental capacities, which depend on critical affective interactions (Table 41–2). These capacities initially emerge in a developmental progression at the ages indicated. In optimal development, as a child grows, he or she continues to develop each capacity to a higher level. Yet, each child may first evidence these processes at ages that are later than expected and/or to different degrees. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Table 41–1 Overview of Clinical Subtypes of NDRC and Related Motor and Sensory-Processing Profile

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>301. Type I</td>
<td>Early Symbolic, with Constrictions: Intermittent capacities for attending and relating; reciprocal interaction; and, with support, shared social problem-solving and the beginning use of meaningful ideas (i.e., with help, the child can relate and interact and even use a few words, but not in a continuous and stable age-expected manner). Children with this pattern tend to show rapid progress in a comprehensive program that tailors meaningful emotional interactions to their unique motor and sensory processing profile.</td>
</tr>
<tr>
<td>302. Type II</td>
<td>Purposeful Problem Solving, with Constrictions: Intermittent capacities for attention, relating, and a few back-and-forth reciprocal interactions, with only fleeting capacities for shared social problem-solving and repeating some words. Children with this pattern tend to make steady, methodical progress.</td>
</tr>
<tr>
<td>303. Type III</td>
<td>Intermittently Engaged and Purposeful: Only fleeting capacities for attention and engagement. With lots of support, occasionally a few back-and-forth reciprocal interactions. Often no capacity for repeating words or using ideas, although may be able to repeat a few words in a memory-based (rather than meaningful) manner. Children with this pattern often make slow but steady progress, especially in the basics of relating with warmth and learning to engage in longer sequences of reciprocal interaction. Over long periods of time, often gradually master some words and phrases.</td>
</tr>
<tr>
<td>304. Type IV</td>
<td>Aimless and Unpurposeful, Similar to Type III above, but with a pattern of multiple regressions (loss of capacities). May also evidence a greater number of associated neurological challenges, such as seizures, marked hypotonia, etc. Children with this pattern often make very, very slow progress. The progress can be enhanced if the sources of the regressive tendencies can be identified.</td>

526. Functional Emotional Developmental Levels
527. Auditory Processing and Language
528. Visuospatial Capacities
529. Regulatory–Sensory Processing Patterns
530. A Combination of the Above Areas

Note: A child may evidence early challenges in a number of areas (e.g., reading, math, and organizing capacities).

4Work Group members included: Sherri Cawn, M.A., CCC-SLP; Sima Gerber, Ph.D., CCC; Cindy Harrison, M.Sc., SLP; Diane Lewis, M.A., CCC-SLP; Jane R. Madell, Ph.D., CCC A/SLP; Stuart G. Shanker, D.Phil.; Amy M. Wetherby, Ph.D., CCC-SLP; Stanley I. Greenspan, M.D.

Axis IV: Language Capacities
Differences in language functioning, just as differences in regulatory–sensory function and family patterns, contribute to the primary symptom patterns of the child. It is also parallel to the functional emotional developmental stages because both are describing the presymbolic as well as the symbolic levels of the child’s overall functioning and communication. The language capacities, including gestural and verbal communication, however, focus on communication, particularly from the toddler through the preschool years.

Axis V: Visuospatial Capacities
This Axis addresses six visuospatial capacities, which develop during infancy and early childhood (preschool) years, which interact simultaneously with the other sensory processing capacities and support or impede emotional and cognitive development. It is important to remember that all the capacities overlap and that the clinician should keep the developmental continuum in mind, as opposed to just focusing on a chronology of milestones. These six capacities are shown in Table 41–3 below. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Axis VI: Child-Caregiver and Family Patterns
Axis VI describes the overall functioning of the caregiver and the degree to which the caregiver is able to support the child’s negotiation of each developmental level. Since caregiver and family patterns affect children in every group of disorders, and not just the interactive disorders, it is included as a separate axis. Table 41–4 outlines the guidelines to observe each caregiver’s interaction with the child.

<td></td>
</tr>
</tbody>
</table>

See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Axis VII: Stress
The purpose of this axis is to identify and consider the possible contribution stress may be having on the presenting symptom patterns. Stressors related to situations, conditions, or events in the family’s (or child’s) life can impact the child’s emotional functioning and development depending on the resources of the child and the family’s ability to mobilize adequate protective factors and support at the time of the stress. The following sequence can be used to assess the impact of the stress.

1. Identify and list the possible sources of stress
2. Determine the onset, severity and duration of the stressors identified
3. Assess the changes in the child’s functioning and mental health possibly influenced by the stressors.

See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Axis VIII: Other Medical and Neurological Diagnoses
Careful listing of medical disorders facilitates the clinician’s thorough investigation and the exploration of possible relationships with the child’s mental health, developmental, and learning challenges. See ICDL-DMIC (Interdisciplinary Council on Developmental and Learning Disorders 2005) for more detail.

Conclusion
The ICDL-DMIC presents an innovative approach to the assessment and diagnosis of infants and young children and their families. It features a multidimensional classification system which uniquely considers the emerging functional emotional developmental capacities of the infant and young child and the developmental pathway to symptom patterns. By also assessing the regulatory, language, and visuospatial capacities of the infant, in addition to stress and medical conditions, the ICDL-DMIC integrates all the interactive aspects of developmental capacities, individual differences, and the impact of relationships.

All that inhabit this great earth,
Whatever be their rank or worth,
Are kindred and allied by birth,
And made of the same clay.

Henry Wadsworth Longfellow, 1878

Introduction
This chapter does not describe a single disease but a heterogeneous set of conditions affecting persons who are characterized by having a pattern of persistently below normal intellectual and adaptive functioning. The study of intellectual disabilities is highly important in psychiatry, as persons with these conditions face increased risks for comorbid mental disorders of all types, the diagnosis and treatment of which often require knowledge of special approaches and skills.

In this chapter, the term “intellectual disability” and “mental retardation” will be used synonymously. Intellectual disability is also considered under the umbrella term “developmental disability” that broadly includes individuals facing disabilities attributable to mental and/or physical impairments with origins before age 22. The term “learning disability” has also been used in the United Kingdom replacing reference to mental retardation. As in the United States, Europe, Canada, and Australia, the use of the term “intellectual disability” is increasingly taking hold, as this is believed to carry less stigmatizing connotation than the term mental retardation. The American Association on Mental Retardation (AAMR) in 2006 has changed its name to the American Association of Developmental and Intellectual Disabilities (AADID). The President’s Committee on Mental Retardation has followed suit as the Committee for People with Intellectual Disabilities. The term intellectual disability is therefore currently universally accepted in both the professional and scientific literature.

The chapter is organized under two major parts. The first part focuses on basic concepts of intellectual disability proper, and the second on issues related to diagnosis, treatment, and prevention of mental disorders in persons with intellectual disability.

INTELLECTUAL DISABILITY

Concept of Intellectual Disability
The following are the basic concepts of intellectual disability and the psychiatric approaches to it, on which this chapter is based:

1. Intellectual disability is not a single or a specific disorder or disease. The term refers to a heterogeneous set of disabilities or conditions that describe the level of a person’s functioning in defined domains. Intellectual disability therefore does not have a single cause, mechanism, course, or prognosis and does not necessarily last a lifetime.

2. Persons diagnosed as having intellectual disability represent a wide spectrum of abilities as well as disabilities, clinical presentations, and behavioral patterns.

3. Persons with intellectual disability do not have unique personalities or behavioral patterns that are specific to intellectual disability, although characteristic behavioral phenotypic patterns may be frequently seen in certain intellectual disability-associated syndromes.

4. Maladaptive behaviors should not automatically be seen as part of the intellectual disability or implying underlying brain disorder. As in all individuals, these behaviors may also be related to life experiences; they
can also be a symptom of mental illness comorbid with intellectual disability.

5. The range of mental disorders experienced by persons with intellectual disability is similar to that among typical persons in the general population.

Although intellectual disability ("mental retardation") is listed as a mental disorder in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000), it is not a unique nosological entity. Intellectual disability is different from other conceptualizations in the DSM by virtue of implying specific underlying assumptions about an affected person's functioning in a normal environment. The diagnosis of intellectual disability refers to the level of a person's current intellectual and adaptive functioning that is below an objective cut-off point. In this sense, by definition, intellectual disability cannot just be a set of behavioral criteria with specific inclusion and exclusion rules, but it entails specific assumptions about a person's cognitive skills and adaptive environment. The diagnosis, although primarily administrative, therefore carries inherent ethical and societal responsibilities in defining a group of persons who are in need of supports and educational services. Thus, intellectual disability or mental retardation, as an Axis II diagnosis in the DSM-IV-TR, cannot have a single cause, mechanism, course, or prognosis. It has to be differentiated from other tangible diagnosis, if known, of underlying medical condition(s) that also need to be listed on Axis III.

Definitions of Intellectual Disability and Its Scientific Evolution

In antiquity, most probably only severe forms of intellectual disability were recognized, or rather physical deformations and disabilities with which it could be associated. Avicenna in the 1st century A.D. recognized that there were various levels of intelligence (Scheerenberger 1983). The Talmud, as early as the 2nd century A.D. recognized that certain persons had significant impairments in cognitive capacity. The "shothet," one of three types of persons with limited capacity (besides deaf and minor) was defined as someone who goes out at night alone, sleeps in the cemetery, and tears own clothes. This was variably interpreted as a person with mental illness or intellectual disability.

Fitz-Herbert, in 1534, suggested what could have been the earliest intelligence test for the diagnosis of intellectual disability: "And he who shall be said to be a sot and idiot from his birth, is such a person who cannot account or number 20 pence, nor can tell who was his father or mother, nor how old he is, etc. so as it may appear that he hath no understanding or reason what shall be for his profit, nor what for his loss" (Scheerenberger 1983). Willis, in the 17th century, recognized that intellectual disability could be of varying degrees: "Some are unable to learn their letters but can handle mechanical arts; others who fail at this can easily comprehend agriculture; others are unfit except to eat and sleep" (Szymanski and Crocker 1989). John Locke, English physician and philosopher, in 1690, differentiated mental illness from mental retardation (which were then commonly seen as one entity) as: "Herein seems to lie the difference between idiots and madmen, that madmen put wrong ideas together and reason from them, but idiots make very few or no propositions and reason scarce at all" (Scheerenberger 1983).

In 1800 when the young French physician, Jean Marc-Gaspard Itard, arrived in Paris, one of his teachers was Philippe Pinel, a founder of modern psychiatry, who had just written an influential book on psychiatric diagnosis promoting the nonviolent management of mental patients, thus originating the concept of "moral" or psychological treatment of mental patients and enriching our understanding of the theory of mental disorders "with all the insights that the empirical approach affords." Itard tried this optimistic empirical approach in the treatment of his much-celebrated patient "Victor of Aveyron." It was subsequently Itard's student Edouard Seguin who later set out to prove that persons with mental and intellectual disabilities were in fact educable. In 1839, Seguin created the first ever-special needs school in Paris dedicated to the education of children with mental disabilities. In 1846, Seguin published his treatise on the "Moral Treatment, Hygiene, and Education of Idiots and Other Backward Children" and subsequently moved to the United States continuing his work with the establishment of his "Physiological School" in New York City. He subsequently served as the first president of the "Association of Medical Officers of American Institutions for Idiotic and Feebleminded Persons" later known as the AAMR (recently renamed AADID). Seguin's work was a major inspiration on Maria Montessori in Rome whose methods subsequently became very influential worldwide on unleashing the social and academic "potentialities" for the early education of children.

In 1905, Alfred Binet and Theodore Simon in France published the first version of what became later the first modern intelligence test. However, it was not designed to assess "intelligence," but rather to predict which children would require and benefit from receiving education through special instruction. They classified children with intellectual disability into four grades of severity, according to the number of test tasks they completed; the later versions gave the child's mental age (Scheerenberger 1983). These tests were soon translated into English and introduced in the United States by Henry Goddard. Many revisions and new tests followed. Lewis Terman's revision of 1916, known as the Stanford-Binet Intelligence Scale, introduced the concept of intelligence quotient (IQ) and classified intellectual disability according to its scores. A number of Terman's initial tests were administered to non-English speaking or nonschooled populations and led to biased "scientific" conclusions that justified discriminatory educational practices at a time of educational segregation and eugenics. Unlike Simon and Binet who emphasized rehabilitation of children, Terman's approach proposed to use IQ scores to classify children according to job expectations.

The first international conference fostering interdisciplinary cooperation in intellectual disability was held in London on the "Scientific Study of Mental Deficiency." The British psychiatrist and medical geneticist, Lionel Penrose, was first to acknowledge the unique importance of the scientific study of intellectual disability in his address by emphasizing that "these unfortunate mentally handicapped individuals can reveal, unwittingly, information of the utmost
value to the rest of the human community, and we may well be grateful to them for their service.” Penrose’s Colchester study, in 1938, was the first scientific study of the genetics of intellectual disability (then termed mental deficiency). His book on Biology of Mental Defect (1949) pioneered the study of various chromosomal causes of intellectual disability including Down syndrome. In a similar light, Arnold Gesell in the United States, both as psychologist, and later as pediatrician, pioneered the importance of empirical and humanitarian study of children’s cognitive development. As a student of Henry Goddard at the Vineland School for persons with mental disabilities he had become interested in studying children with disabilities. He became interested on aspects of nature and nurture and was one of the earliest scientists to caution against prematurely attributing mental disabilities to specific causes. Gesell was also an early proponent for establishment of a nationwide system of early preschool education in the United States that saw the seeds for the subsequent inception of Head Start programs. In 1949, Gesell argued that the “developmental philosophy of child care should have far-reaching implications for a better understanding of ourselves” and of our “democratic way of life.” The roots of a societal commitment in the United States to the care and education of persons with special needs was thus emerging.

Definition of Intellectual Disability (AAMR or AADID)

Since its inception, the AAMR has published 10 definitions of intellectual disability. The initial 1910 definition required the presence of a “mental defect” and an inability to manage ordinary affairs (corresponding to today’s impairment in cognitive capacity and adaptive behavior), this included the classifications of “idiots” (mental age of 2 years or younger), “imbeciles” (mental age of 2–7 years), and “morons” (mental age of 7–12 years). The definition published by AAMR, in 1959, proposed three diagnostic criteria: subaverage intellectual functioning, impairment in adaptive behavior, and onset in the developmental period (Heber 1959). The subaverage intellectual functioning was meant to be one standard deviation or more below the population mean (IQ of approximately 85), and the developmental period referred to age 16 years or less. Five degrees of severity of mental retardation based on the IQ scores were introduced: borderline, mild, moderate, severe, and profound. In 1973, the definition was again changed in that the IQ cut-off point was 2 standard deviations (approximate IQ of 70), thus eliminating the category of “borderline mental retardation.” The developmental period was increased to 18 years or younger. As the result of these changes, the number of persons who could be labeled as having intellectual disability (mental retardation) thus decreased considerably.

The current definition, published in 2002 is as follows:

The AAMR Definition of Mental Retardation (American Association on Mental Retardation 2002)

Mental retardation is a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills. This disability originates before age 18.

Five Assumptions Essential to the Application of the Definition:

1. Limitations in present functioning must be considered within the context of community environments typical of the individual’s age peers and culture.
2. Valid assessment considers cultural and linguistic diversity as well as differences in communication, sensory, motor, and behavioral factors.
3. Within an individual, limitations often coexist with strengths.
4. An important purpose of describing limitations is to develop a profile of needed supports.
5. With appropriate personalized supports over a sustained period, the life functioning of the person with mental retardation generally will improve.

Significant limitation in intellectual functioning is defined as at least 2 standard deviations below the mean as measured by the assessment instrument. The standard error of measurement for the instrument (usually between 3 and 5 points) should be taken into consideration. Persons with intellectual disability can be classified in various ways such as by IQ levels, or intensity of supports they require, depending on the purpose for which the diagnosis is used. Significant limitation in adaptive behavior is defined as performance of at least 2 standard deviations below the mean on an instrument based on general population norms. This manual emphasizes the requirement for detailed assessment of individuals and their needs in all relevant domains, including psychological and emotional, and is by far the most modern and comprehensive available.

DSM-IV-TR Definition

DSM-IV-TR (American Psychiatric Association 2000) defines mental retardation (intellectual disability) in a manner generally compatible with the AAMR definition, however, subclassification into degrees of severity is retained. Intellectual disability is coded on Axis II, as conceptually it is thought to fit more congruently with personality disorder conceptualization listed here, than with mental illnesses listed on Axis I. It was also expected that placement on Axis II will encourage clinicians to diagnose both intellectual disability and mental disorders when faced with a person who has such comorbidity, rather than these latter conditions being conveniently subsumed under the diagnosis of intellectual disability.

International Classification of Diseases Definition (ICD-10)
The ICD-10 definition uses a rather outdated language based only on IQ estimated by intelligence tests; adaptive behaviors are mentioned only in supplementary roles. The definition is as follows: “A condition of arrested or incomplete development of the mind, which is especially characterized by impairment of skills manifested during the developmental period, skills which contribute to the overall level of intelligence, that is, cognitive, language, motor, and social abilities. Retardation can occur with or without any other mental or physical condition” (World Health Organization 2006). There are five subcategories, based on IQ levels:

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria
The method of defining the level of severity differs slightly between the two systems. The ICD-10 Diagnostic Criteria for Research define the levels using exact cut-off scores: Mild is defined as 50–69, Moderate is defined as 35–49, Severe is defined as 20–34, and Profound is defined as below 20. In contrast, DSM-IV-TR provides somewhat greater flexibility in relating severity to a given IQ score by defining severity levels using overlapping scores (i.e., mild is 50–55; moderate is 35–40 to 50–55; severe is 20–25 to 35–40; and profound is below 20–25). Within the overlapping range, the severity is determined by the level of adaptive functioning.

Contrasting Definition of Developmental Disability
The term “developmental disability” is in fact an administrative one; it is nevertheless often used interchangeably with intellectual disability or mental retardation. The term was defined in the Developmental Disabilities Assistance and Bill of Rights Act (2000) as: severe, chronic disability due to a mental or physical impairment; manifested before age 22; likely to continue indefinitely; resulting in substantial functional limitations in three or more of the major life activities (as in self-care, receptive and expressive language, learning, mobility, self-direction, capacity for independent living, and economic self-sufficiency). In contrast to the narrower term intellectual disability, the notion of developmental disability is therefore not dependent on standardized measures of intelligence or adaptive function. Thus not every case of intellectual disability is a developmental disability, unless severe functional limitations are also present.

Prevalence of Intellectual Disability
There have been various models for estimating the prevalence of intellectual disability. A model based on IQ score alone used the expected statistical distribution of intelligence levels. The past definition based only on an IQ that was 1 standard deviation or greater below the mean implied that almost 15% of the population could be classified as having intellectual disability. With the introduction of the diagnostic criterion of impairment in adaptive behavior and an IQ cutoff at 2 standard deviations below the mean (approximately 70), the prevalence of intellectual disability was commonly thought to be about 2.3% of the population (Larson et al. 2001). More recent population-based studies, using multiple methods of ascertainment and a current definition of intellectual disability, suggest that the prevalence might be closer to 1%. In the study of McLaren and Bryson (1987), the prevalence of mild intellectual disability was 0.37–0.59%, whereas the prevalence of moderate, severe, and profound intellectual disability was 0.3–0.4%. Based on results of the 1994/1995 National Health Interview Survey Disability Supplements (NHIS-D), Larson et al. (2001) estimated the prevalence of intellectual disability in noninstitutionalized population of the US to be 0.78%. When age is considered, the highest prevalence is in the school-age group, when the child cannot meet the expectations of academic learning. United States Department of Education indicated the prevalence of intellectual disability among school-age children (6–17 years of age) to be 1.14%, with variations reported by different states (Massey and McDermott 1995). Conversely, some persons who are diagnosed with mild intellectual disability when of school age lose that diagnosis in adulthood when their good adaptive skills are more relevant than their academic achievement. However, prevalence based on administrative data (e.g., attendance in special education classes), may not be accurate. For example, children with intellectual disability and comorbid conditions such as autism may in fact carry solely a diagnosis of autism, as this may be considered less stigmatizing.

Patterns of Comorbidity
Other mental and physical disorders frequently cooccur or are truly comorbid with intellectual disability. Intellectual disability may be part of the clinical manifestation of a given disorder or syndrome. Alternatively, an insult to the Central Nervous System (CNS) might cause both intellectual disability and another disorder; examples may include seizures.

CNS Problems
Intellectual disability reflects in part the function of the CNS. Sometimes there are discrete lesions that are identifiable, and at other times brain morphology appears normal on routine imaging tests. It is common for individuals with intellectual disability to also have other medical, developmental, and behavioral issues. These conditions may be part of the same etiologic presentation or associated with it. A person with intellectual disability, with cognitive and adaptive skill
functioning significantly below age expectation, may also have delays in other developmental domains such as language, gross motor, fine motor, and social skills. There often is overlap in at least some of the domains. For example, an individual with autism may have intellectual disability in addition to disturbances in the domains of communication, social skills, and behavior. A person with cerebral palsy (CP) may also have intellectual disability, along with speech and language impairment. Table 42–1 summarizes the early studies demonstrating the association of various disorders with mild and severe intellectual disability. It is to be noted that the additional disabilities are more often associated with severe than with mild intellectual disability because of the more severe pathological brain condition. Petersen et al. (2007) have also found an increased risk for congenital anomalies in all children with intellectual disability compared to the general population, although more notable in those with more significant cognitive impairment.

**Motor**

CP, the commonest motor manifestation, is defined as a “disorder of movement and posture secondary to a static encephalopathy, with the insult to the brain occurring prenatally, perinatally, or in early childhood (Taft and Matthews 1992). While CP represents a nonprogressive CNS insult, there may be aspects of motor and other system function that do change over time. CP has been associated with hypoxic–ischemic events during labor and delivery, however, there are often other causes (Nelson 2002). Advances in brain imaging techniques (computerized tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET)) have greatly improved the possibilities to ascertain the etiology and pathology of CP. Perinatal risk factors include the premature infant with positive findings on cranial ultrasound or evidence of periventricular leukomalacia, perinatal hypoxic-ischemic encephalopathy in the full-term infant, neonatal seizures, and cortical arterial infarct (Wood 2006). Some children do not have these risk factors, although etiologic factors may include infections, genetics, metabolic disorders, toxic exposures, and trauma.

Individuals with CP may have cognitive skills within or above normal range, or may have intellectual disability ranging from mild to profound. The reported proportion of children with CP who also have intellectual disability varies widely due to differences in study populations and diagnostic criteria. Overall, approximately 20% of persons with intellectual disability also have CP. When the motor difficulties are severe, other medical problems may arise. Individuals may have disorders of the feeding and digestion, consisting of problems with chewing, swallowing, gastroesophageal reflux, gastric mobility, and aspiration. There may be chronic respiratory issues, due to difficulties clearing secretion. The presence of spasticity contributes to difficulties with ambulation and increases the likelihood for development of scoliosis, hip displacement, and joint contractures. Motor speech disorders may exist, affecting communications skills and speech intelligibility.

**Language**

While communication has a motor component, there is also a more symbolic aspect of language that affects the ability to understand language and express oneself both verbally and nonverbally (Costello 2006). Individuals with profound intellectual disability may be nonverbal, although nonverbal communication such as gestures or facial expressions may be used. Other individuals are able to use augmentative communication devices, operating switches or using keyboards to express their wishes. Language disorders may occur in the context of cognitive and hearing impairments, as well as genetic disorders, brain injury, and other conditions that may affect neurological functioning.

**Behavior**

Individuals with intellectual disability have been found to have a higher rate of behavioral and psychiatric disorders compared to the general population. Thirty to forty percent of individuals with intellectual disability have been reported to present with behavioral abnormalities (Dykens and Hodapp 2001). Specific behavioral profiles have also been identified in individuals with syndromes associated with intellectual disability. Self-injurious behaviors (SIB) as a rule are not commonly seen in the general population. Individuals with intellectual disability, particularly those with more severe intellectual disability, and individuals with autism and certain psychiatric disorders may present with SIB (Schroeder et al. 2001). Repetitive behaviors such as rocking or stereotypic hand movements may be seen in individuals either with significant intellectual disability or autism. While reduced attention may be seen in individuals with intellectual disability, attention may also be commensurate with level of cognitive function and significant language processing difficulties. There also is an increased incidence of intellectual disability in children with autism and autism spectrum disorders, including pervasive developmental disorder not otherwise specified (PDD-NOS) with estimates ranging from 50–75% (Johnson and Walker 2006).

**Seizures**

Seizure disorders are seen in 0.5% of the general population and in approximately 20% of persons with intellectual

</table>
disability. There is a direct relationship between the level of cognitive functioning and incidence of seizure disorders. Seizures represent an abnormal conduction of neurophysiologic signals associated with significant brain anomalies, as well as more subtle disruptions in neuronal connection. As intellectual disability reflects CNS function, it is not surprising that there is an increased incidence of seizure disorders in those with intellectual disability.

The type of seizure may also provide both prognostic and etiologic information. “Infantile spasms” are often seen in children with significant disabilities and generally carry a poor prognosis, with later development of Lennox-Gastaut syndrome, or infantile seizures, associated with such conditions as Tuberous Sclerosis (or Tuberous Sclerosis Complex) (TSC). Myoclonic seizures, in turn, may be associated with metabolic disorders. Complex-partial seizures are associated with behavioral and sensory manifestations, including illusions, hallucinations, and alterations in consciousness and awareness. Intercital changes may include mood changes, anxiety, as well as fear, elation, or depression. Problems with attention, focus, behavioral outbursts, and regression of developmental skills may be associated with undiagnosed and treated seizure disorders. These may be difficult to distinguish at initial examination in an individual with intellectual disability with pre-existing cognitive and behavioral difficulties and may be overlooked. Long-term encephalographic recording by telemetry with simultaneous videotaping of behavior may be performed to clarify the possible relationship between the seizures and the behavior in question. At times, seizure control may require more than one anticonvulsant trial or a combination of anticonvulsants. There always needs to be a balance between control of seizures and medication-related side effects, which may include tiredness, somnolence, irritability, behavioral, and cognitive problems, as well as abnormalities in blood chemistries and hematological indices.

Sensory Impairments
Sensory problems are common in persons with intellectual disability, although the prevalence data vary greatly. Hearing loss may be present with different genetic, metabolic, infectious, and acquired etiologies, and may be associated with intellectual disability (Neault 2006). Hearing loss may be sensorineural or conductive, and, in turn, may be congenital or acquired. Reliable hearing assessment needs to be done on any child with language delay even in the context of a medical diagnosis for his or her presentation. Appropriate medical evaluation to determine a potential unifying biomedical cause of intellectual disability varies from person to person, as well as abnormalities in blood chemistries and hematological indices.

Sensory Impairments
Sensory problems are common in persons with intellectual disability, although the prevalence data vary greatly. Hearing loss may be present with different genetic, metabolic, infectious, and acquired etiologies, and may be associated with intellectual disability (Neault 2006). Hearing loss may be sensorineural or conductive, and, in turn, may be congenital or acquired. Reliable hearing assessment needs to be done on any child with language delay even in the context of a normal neonatal hearing screen. Visual impairment due to retinopathy of prematurity (ROP) may occur in infants born prematurely due to oxygen use. Optic atrophy, with associated visual impairment, is also often identified in individuals with significant intellectual disability associated with brain abnormalities. Visual impairments have been found to be as high as 50% in individuals with intellectual disability when strabismus and refractive errors are included.

Etiology and Pathophysiology of Intellectual Disability
General Considerations
A variety of biomedical insults can disrupt the integrity of the CNS and affect cognitive function. It should be kept in mind, however, that the diagnosis of intellectual disability takes into account a persons’ overall level of functioning, encompassing current intellectual and adaptive skills, as well as the intensity of needed levels of support (American Association on Mental Retardation 2002). A person’s general state of health, associated disabilities, environmental supports, and psychological factors may all affect a person’s ability to function independently. While congenital or acquired etiologic factors may be the primary cause for cognitive delays, these other factors may impact a person’s functional outcome.

It is important to understand the primary etiology for a person’s intellectual disability for a number of reasons:

- Treatment possibilities such as early implementation of a phenylalanine-free diet in phenylketonuria (PKU) or thyroid hormone replacement in congenital hypothyroidism, both of which may result in intellectual disability if untreated.
- Prevention such as primary prevention of the recurrence of a condition such as developmental delays secondary to fetal alcohol syndrome (FAS).
- Genetic counseling for the family regarding recurrence risk of particular disorders such as maternal transmission of Fragile X syndrome (fraX).
- Early recognition and treatment of complications known to be associated with the particular presentation or syndrome such as hypothyroidism in Down syndrome.
- Research on causation and prevention.
- Impact on public policy for development of community supports.
- Prognostic information provided to families regarding the natural or anticipated trajectory of a particular disorder.
- Support for the family and other caregivers dispelling misconceptions and anxieties related to the uncertainty about the cause.

For these reasons, it is important for physicians, including psychiatrists, to ascertain whether a person with intellectual disability to whom they provide care has had appropriate medical evaluation to determine a potential unifying medical diagnosis for his or her presentation.

Approaches to Classification of the Causation of Intellectual Disability
Many of the classification systems for intellectual disabilities have been based on the timing of the insult to the CNS. This approach was used by Yannet (1945) who divided the causes into prenatal, perinatal, and postnatal, plus genetic. In Heber’s classification (Heber 1959), more emphasis was put on the presumed nature of the intellectual disability. The eight main categories were: (1) infection, (2) intoxication, (3) trauma or physical agent, (4) disorder of metabolism, growth, or nutrition; (5) new growths, (6) unknown prenatal influences, (7) unknown or uncertain cause, with the structural reactions manifested, and (8) an uncertain or presumed psychological cause, with the functional reaction alone manifested. The successive classification systems developed by AAMR also follow the timing approach (American Association on Mental Retardation 2002).

Some reports indicate that the prevalence of diagnosable biomedical causes of intellectual disability varies...
with the degree of the disability. Identifiable etiologies for individuals have varied greatly, based on differences in samples, methods of assessment, and diagnostic criteria. Severe intellectual disability has long been associated with prenatal etiologies in 59–73% of patients, although such a cause has been reported in 23–43% of individuals with mild intellectual disability (Table 42–2). The classification used here by Welska and Kaski (1999, 2001) reflects both the timing and the type of the causative process, which will affect the development and function of the CNS (Table 42–3). However, with newer diagnostic and genetic tests, etiology has been reported to be identifiable in 50% of individuals presenting at a tertiary care center, regardless of level of cognitive skills (van Karnebeek et al. 2005). The goals of the etiologic evaluation are to elucidate the earliest developmental cause as well as other coexisting factors because their effects are usually interactive and cumulative (McLaren and Bryson 1987).

### Prenatal Causes

There may be prenatal causes of intellectual disability that may be genetically determined, may represent a de novo genetic mutation, may be multifactorial, or may result from an intrauterine insult that affects fetal development such as

exposures to toxins or teratogens, infections, abnormalities in perfusion, or poorly controlled metabolic disorders.

**Chromosomal Disorders**

Chromosomal evaluations are performed cytopgenetically; the normal karyotype being 46 XX or 46 XY. Abnormalities in the number of chromosomes may result in disorders that affect cognition or learning, and may result in syndromes that cause intellectual disability. There may be additional chromosomes (polyploidy) or missing chromosomes (monosomy). Monosomy of autosomal chromosomes is incompatible with life, although monosomy of a sex chromosome (XO) may result in a syndrome that is not generally associated with intellectual disability (Winnepenninckx et al. 2003).

Down Syndrome. Down syndrome is the most common polyploidy and chromosomal disorder that causes intellectual disability (Johnson and Walker 2006). The vast majority of individuals with Down syndrome are found to have an extra chromosome 21 on cytogenetic testing. In trisomy 21 the extra chromosome in the egg or the sperm results from nondisjunction in the meiotic stage. When such a gamete becomes fertilized the fetus will have an extra chromosome 21 in all cells for a total of 47 chromosomes. In mosaicism, some cells have 47 chromosomes, and others have 46 because of an error in one of the first cell divisions of the fertilized egg. The percentage of cells with trisomy 21 may vary, which may then have an effect on the phenotypic presentation and the degree to which a person is affected by the syndrome; children with normal intelligence have been described.

The common physical characteristics of a person with Down syndrome are upward-slanted palpebral fissures, flat and low nasal bridge with epicanthal folds, small mouth and ears, transverse palmar creases, short and wide palms, and a characteristic dermatoglyphic pattern (Figure 42–1). Children with Down syndrome present with significant hypotonia that affects acquisition of motor milestones, as well as notable delays in expressive language skills. The degree of intellectual disability varies from severe to mild with a mean IQ of approximately 50; most children have mild to moderate intellectual disability. Down syndrome occurs in 1 in 800 live births, although increases significantly with maternal age 35 years and older. The incidence in women older than 40 years of age is approximately 1 in 40 live births. As the majority of children born with Down syndrome are from mothers who are less than 35 years of age, the

![Figure 42–1 A young man with Down syndrome and a trisomy 21 karyotype](image)
American College of Obstetrics and Gynecology recently recommended that all pregnant women be offered screening tests that would identify a fetus with Down syndrome (American College of Obstetrics and Gynecology 2007).

Children with Down syndrome present as adorable, affectionate, and generally quite social. Individuals with Down syndrome, however, may also present with various behavioral and psychiatric problems. Younger and less verbal children have been diagnosed with problems with attention deficit hyperactivity disorder and oppositional behavior. Older and more verbal adolescents and adults are vulnerable to pathological grief responses in the face of traumatic loss, as well as generalized anxiety and major affective disorders, often also leading to a regression in adaptive functioning. Approximately, 7% of children with Down syndrome also meet diagnostic criteria for autism spectrum disorders (Johnson and Walker 2006). The prevalence of autism-like behaviors increases with increasing severity of intellectual disability. Early diagnosis and intervention, including speech and language, occupational, physical, and behavioral therapies and developmental stimulation, are essential to enable these children to reach their developmental potential.

Individuals with Down syndrome are at risk for a number of associated health problems. It is important to be aware of this to enable early diagnosis and treatment as well as prevention. The Committee on Genetics of the American Academy of Pediatrics (AAP) has recently published guidelines concerning health supervision for children with Down syndrome, in order to identify these potential medical problems throughout a person’s lifetime (American Academy of Pediatrics 2001). There is an increased risk for congenital heart defects (40–50% of persons), gastrointestinal atresias (in 12%), Hirschprung disease (<1%), and leukemia (<1%). Hearing loss, mostly conductive, secondary to otitis media (75%) requires identification and treatment in order to avoid additional factors that negatively impact speech and language development. Respiratory and ear infections are common, partially attributable to anatomical features and to deficiencies in cellular immunity. Obstructive sleep apnea is seen frequently among persons with Down syndrome. Infants with Down syndrome have an increased risk of congenital cataracts compared to the general population (Kallen et al. 1996), which become more frequent and may significantly affect vision with increasing age into adulthood (Fulton et al. 2006). Approximately 50% of individuals have ocular findings. The subject’s age, specific intellectual disability (ID) syndrome, and severity of cognitive impairment have all been noted to be related to higher prevalence of ocular disorders. The most frequently reported ocular findings include optic atrophy, cataract, keratoconus, and strabismus; in addition, the most prevalent refractive error was hypermetropia (Pires da Cunha et al. 1996). Gluten intolerance is diagnosed in 4–20% of individuals with Down syndrome and should be kept in mind in cases of gastrointestinal problems. Atlanto-axial instability (AAI) is seen in 10% of individuals with Down syndrome, and potentially could result in sensory or motor neurological problems. While there is some difference of opinion regarding screening for AAI, most providers follow AAP guidelines based on requirements for participants in Special Olympics. Cervical spine X-rays are recommended between the ages of 3 and 5 years, before participation in sports activities. They are also recommended with onset of related neurological symptoms and prior to general anesthesia (Martin 1997). Hypothyroidism may be congenital or may develop later, the incidence increasing with age. It may negatively affect cognitive function, and is treatable with thyroid replacement therapy. Regular thyroid function screening is therefore recommended.

Overall, the quality of life and the life expectancy for individuals with Down syndrome has improved markedly in recent decades due to improved living conditions, developmental and educational interventions, availability of antibiotics, and possibilities for surgical correction of anomalies, especially those affecting the heart. Adults with Down syndrome may have cognitive decline associated with neuropathological changes of Alzheimer’s type dementia at a relatively early age. However, the neuropathological changes may not necessarily be accompanied by clinical symptoms of dementia until the 5th or 6th decade of life (Alvarez 2006).

Partial Chromosomal Anomalies. A person may have a normal number of chromosomes with structural changes of the chromosome itself. There may be deletions, in which the part of the chromosome that is missing can be visualized with a microscope. There may be inversions, in which a portion of the chromosome has broken off and the inverted section become part of the chromosome. There are also ring chromosomes in which there may be deletions at both ends that subsequently unite. A translocation reflects the part of a chromosome transferred to another one.

In cases of Down syndrome caused by unbalanced translocation there are 46 chromosomes. However, chromosomal material from 47 chromosomes is present because an extra chromosome 21 is attached (translocated) to another chromosome, usually chromosome 14 (designated as t(14;21)). In about half of translocation cases a parent (usually the mother) has a balanced translocation: 45 chromosomes with t(14;21). If a child has Down syndrome due to a translocation, the parents should be examined for the presence of a balanced translocation. This is important in genetic counseling because when the mother or father has a t(14;21) translocation, there is a high risk of having a child with Down syndrome. The characteristic phenotype of Down syndrome is basically the same in trisomy 21 and in translocation.

In situations in which there is a deletion, the presentation of the person may vary based on the size and location of the deletion on the chromosome, although it is usually associated with intellectual disability (Winneppeninckx et al. 2003). The best-known example of a chromosome deletion syndrome is cri du chat syndrome, which is characterized by a high-pitched voice and is caused by a deletion in chromosome region 5p15.2–p15.3.

Ring chromosomes occur when the ends of the chromosome fuse together. In addition to complete monosomy seen in Turner syndrome, 45, XO, there are also instances in which ring X chromosome results in partial monosomy. While Turner syndrome is usually associated with learning disabilities, particularly on performance tasks, girls with ring chromosome have presented with intellectual disability, as well as other cognitive and behavioral disorders (Moldavsky
et al. 2001). It should be noted that most fetuses with chromosomal aberrations are not viable. About 40–50% of spontaneously aborted fetuses have a chromosomal anomaly.

**Malformation Syndromes due to Microdeletions**

These syndromes had previously been classified as malformation syndromes of unknown origin (see later in the chapter), but because of the described findings of microdeletions, they are now placed in a separate category between chromosomal aberrations and monogenic mutations (Table 42–4).

Microdeletions refer to loss of a few genes, and are not visible cytogenetically. The use of DNA probes and fluorescence in situ hybridization (FISH), in which the chromosomes are treated with specific fluorescent dyes to reveal deviant genes, has brought new light to many of the malformation syndromes previously classified as being of unknown origin. FISH studies are often used when a particular disorder or syndrome is suspected based on the phenotypic or clinical presentation. The same submicroscopic deletions (microdeletions) of DNA have been reported in chromosome 15q11–13 in the **Prader–Willi syndrome** and **Angelman syndrome**. In Prader–Willi syndrome, the paternally derived information at that site is usually absent, although it may also be associated with maternal unisomy or, less frequently, when each of the two chromosome 15 are from the mother. With Angelman syndrome, there is missing maternal information, from maternal deletion, or less frequently, from paternal uniparental disomy (Dykens and Hodapp 2001). Mutations may also be seen in the UBE3A gene (Moldavsky et al. 2001). Individuals with Angelman syndrome may present with moderate to profound intellectual disability, are nonverbal, ataxic, frequently laugh, and hold their arms flexed in such a manner to sometime be referred to as Happy Puppet syndrome. Infants with Prader–Willi syndrome are generally hypotonic, feed poorly, and present with small hands and feet. They later exhibit excessive appetite and hyperphagia that lead to severe obesity. Prader–Willi syndrome is usually associated with mild to moderate intellectual disability. Approximately 70% of the individuals with these syndromes have de novo deletions without recurrence risk in the family. The rest have several complicated genetic patterns that need advanced techniques for diagnostic assessment. Because this syndrome has no clear pathognomonic features it may remain undiagnosed and such individuals might even be referred for psychiatric treatment because of an eating disorder. Obviously, psychological factors are not the primary cause here but supportive psychotherapy might be helpful. The treatment is based on behavioral modification and imposing strict environmental limits on food intake, as well as necessary educational programming.

Initially it was found that one of four persons with the **Rubinstein–Taybi syndrome** had a microdeletion in chromosome 16p13.3 (Breuning et al. 1993). However, it has been discovered that only a small percentage of these patients have deletions that are identifiable with usual chromosome or FISH studies, with others having abnormalities at the molecular level. This microdeletion syndrome has been found to be due to inactivation of a single gene (Ligon et al. 1997).

*CHD, Congenital heart disease.

Microdeletion of 7q11.23 is present in 90–99% of individuals with Williams syndrome. The visuospatial abnormalities that are specifically associated with this syndrome may be due to loss of the LIM-kinase I gene (Moldavsky et al. 2001). The phenotype of the Williams syndrome includes short stature, aortic stenosis or other congenital heart defects, and hypercalcemia in childhood. The facial appearance is characteristic and may include periorbital fullness, a long philtrum (groove on upper lip), full lips with open mouth, a stellate iris pattern, and early graying of hair. The behavioral phenotype may also be characteristic and includes an outgoing personality and overwhelming talkativeness that might even tax the caregivers’ patience. The symptoms vary, however, and even autistic disorder and aggressiveness have been found in these individuals.

Velocardiofacial syndrome (VCFS), also called Shprintzen or CATCH 22 syndrome is usually associated with microdeletion at chromosome 22q11.2 (Ligon et al. 1997). It has been associated with cleft palate, velopharyngeal incompetence, congenital heart or major vascular anomaly, hypocalcemia, and immunodeficiency. Persons with this syndrome often have normal cognitive skills, although may present with language and motor delays as a young child, learning disabilities when older, and less frequently with intellectual disability (Wang et al. 2000). This syndrome is associated with a significant risk for psychiatric disorders including bipolar disorder, major depression, and other psychoses. The prevalence of VCFS is estimated to be 1 in 2,000 live births, thus it should be considered in the differential diagnosis of psychiatric patients.

Submicroscopic Rearrangements

The telomeres of chromosomes are rich in genes and possess characteristics that lend themselves to imbalances. Tests evaluating the subtelomeric area, or functional end of the chromosome, have been used to identify submicroscopic abnormalities that are not visible with standard techniques. The application of FISH to the subtelomeric area of all chromosomes has been used to identify abnormalities such as deletions, duplications, and translocations in these areas. It has been reported that 7.4% of children with moderate to severe intellectual disability and normal karyotype testing will have an identifiable subtelomeric abnormality. It has been suggested that between 4% and 35% of apparently idiopathic intellectual disability is a result of rearrangements in the subtelomeric area (Sogaard et al. 2005, Moeschler and Shevel 2006, Velagaleti et al. 2005, Shoumans et al. 2005). Many clinicians will obtain subtelomeric FISH studies in children with intellectual disability without an identifiable etiology when chromosome analysis is normal (Moeschler and Shevell 2006); others performed this test with additional criteria, particularly in the context of dysmorphology of severe ID and a family history of developmental delay (Sogaard et al. 2005, Velagaleti et al. 2005).

Genomic microarrays, or comparative genomic hybridization (CGH), is a newer technique that evaluates structural abnormalities on the entire chromosome (Moeschler and Shevell 2006). Identification of submicroscopic chromosomal abnormalities has been reported to occur in 15–24% of patients with idiopathic intellectual disability (Shoumans et al. 2005). CGH has been used to characterize known genetic syndromes such as identifying the CHD7 gene responsible for Coloboma of the eye, Heart defects, Atresia of the choanae, Retardation of growth and/or development, Genital and/or urinary abnormalities, and Ear abnormalities and deafness (CHARGE) syndrome. It has been used to characterize subtelomeric imbalances such as Williams syndrome (Moeschler and Shevell 2006). This technique has been also used in lieu of subtelomeric FISH testing. Array-CGH has been utilized to identify chromosomal changes idiopathic ID in whom prior testing has been negative.

Comparative genomic hybridization testing is used as an adjunct, not a replacement, for other genetic tests. (Mao and Pevsner 2005). High resolution karyotype and other FISH studies continue to play important roles in the evaluation of ID. While CGH may identify abnormalities not visible with other methods, there are also single nucleotide polymorphism (SNP) oligonucleotide arrays that have been used for rapid molecular karyotyping of a small amount of DNA to detect subtle deletions and duplications (Rauch et al. 2004).

Syndromes due to microdeletions had previously been classified as malformation syndromes of unknown origin, but because of the described findings of microdeletions, they are now placed in a separate category between chromosomal aberrations and single gene defects (Table 42–4).

Single Gene Defects

A mutation in a single gene results in defective enzymes or proteins. These defects may cause an accumulation of substrate, inability to stop the formation of a damaging end product or block the production of a needed substrate. There may be defects in receptor or transport systems, as well as alterations of proteins. Inheritance of these monogenic mutations may be autosomal dominant, autosomal recessive, X-linked, or mitochondrial.

Disorders with Autosomal Dominant Inheritance

Tuberous Sclerosis Complex

TSC is an example of the disorders in this group associated with intellectual disability. It is caused by a mutation in a gene affecting the formation of the ectodermal layer of the embryo. Because the skin and the CNS develop from this layer, abnormalities are seen in both. The skin lesions include angiofibromas in the form of macules on the cheeks (adenoma sebaceum), with a butterfly-like distribution, especially after puberty. Café au lait macules or nonpigmented ash leaf-shaped areas are also found. Intellectual disability, epilepsy, and calcifications in the brain are seen, as are tumors. Epileptic seizures often begin as infantile spasms, which alert the physician to look for other symptoms of this disorder. If TSC is diagnosed, both parents should be examined carefully because the mutation is inherited in about 25% of cases. Because of the dominant inheritance, the risk of recurrence is 50% for each pregnancy among affected families. The expression of this gene mutation varies from small skin discolorations (which may indicate a carrier state) to multiple disabling conditions. It is a relatively rare disorder (with a prevalence of 1 in 30,000 to 1 in 50,000 live births), but it may be found in about 0.5% of persons with severe intellectual disability. The early onset infantile seizures, anatomical location of tubers in the temporal lobe, or associated disruption in the temporal lobe function, are all
predictive of a greater degree of onset of autism spectrum disorders or autism-like symptoms. The seizures therefore need to be treated proactively.

**Other Disorders with Autosomal Recessive Inheritance**

Most metabolic disorders belong to this category. They are caused by single mutated genes that disturb the metabolism by deficient enzyme activity. The risk of healthy carrier parents having an affected child is 25% for each pregnancy. The diagnosis is made by detection of abnormal metabolic products in the urine, blood, or tissues and/or by low or absent enzyme activity. When there is high clinical suspicion and the possibility of gene detection, direct DNA techniques might be used. The metabolism of amino acids, carbohydrates, lipids, and mucopolysaccharides are affected in different disorders. A few examples of inborn errors of metabolism are given in Table 42–5.

PKU is the best known and most common of the metabolic disorders. The incidence of PKU varies among populations. The incidence in the US is 1 in 8,000 live births among Whites and about 1 in 50,000 live births among African-Americans. The enzymatic defect is diminished activity of phenylalanine hydroxylase, which leads to a high serum phenylalanine level affecting, among other things, myelination of the CNS. The phenylalanine hydroxylase gene has been mapped to 12q22–24.1. Prenatal diagnosis and carrier detection are possible, and all newborns are screened for PKU in most developed countries. It was described in 1934 by Folling in ten children with ID, hypertonia, and hyperreflexia, with a musty odor in urine and sweat. Seizures and tremors are common, as are eczema and psychotic manifestations. The clinical symptoms can be prevented by use of a low-phenylalanine diet soon after birth. Increasingly, a lifelong low-phenylalanine diet is recommended to prevent later deterioration in cognitive functions. Women with PKU who are successfully treated do not have clinical manifestations themselves but still have phenylalanine blood levels high enough to cause brain damage to a fetus if they become pregnant. To avoid this, strict adherence to the diet is important before they become and during pregnancy. The diet requires restriction

*All disorders cause mental retardation except that in homocystinuria it does not occur in every case. Dietary treatment benefits patients with PKU and galactosemia. Prenatal diagnosis is available for all disorders. Inheritance is autosomal recessive, except for MPS II and Lesch-Nyhan, which are X linked. I, Infancy; A, adulthood; U, urinary; MR, mental retardation.

of proteins, including meats, fish, milk, bread, cake, nuts, and even vegetables. A phenylalanine-free dietary supplement is required to ensure adequate nutritional support, which may be unpleasant for some and may also produce side effects (Levy 1999). There are new treatments that are being developed that would allow for a less restrictive diet such as an oral agent phenoptin (6R-BH4) that would potentially reduce blood levels phenylalanine levels (Shuett 2004).

X-Linked Intellectual Disability
X-linked intellectual disability may occur as often as 1 in 5000 males; it is felt to account for 10–20% of intellectual disabilities that are inherited (Winnepenningckx et al. 2003). While Down syndrome is the most common congenital form of intellectual disability, fraX is the most common inherited form of ID. The estimated prevalence is 1 in 4000 males and 1 in 6000 females (Walker and Johnson 2006), although other studies have estimated the female prevalence to be half that seen in males (American College of Medical Genetics 2006).

FraX was first reported by Lubs (1969) and was connected to the clinical syndrome by Harvey in 1977 (Harvey et al. 1977). Because of a constriction at the location Xq27.3, the FRAXA site, it appears as if the chromosome is fragile and a part of it is breaking off. Demonstrating this phenomenon requires a folate-poor cell culture/medium. It has been studied more consistently since the early 1980s when the connection with folate-poor medium was identified. Methylation of fully mutated gene causes inactivation of FMR1-protein (FMR1P), which is the basic defect in the fraX (Tassone et al. 1999). The FMR1P has been noted to be involved in both pre- and postnatal development of the brain (Dykens and Hodapp 2001).

The genetic defect involved in the fragile X-linked mental retardation has been traced to the FMR1 gene, an unstable region in which there is a mutation consisting of repeats of the triplet nucleotide cytosine-guanine-guanine (CGG). The normal X chromosome contains 5–50 copies of this triplet; asymptomatic female or male carriers have 50–200 copies (premutation), and affected individuals have over 200 copies (full mutation). The range of the triplet repeats can be demonstrated by the Southern Blot Technique, which is used for the diagnosis of fraX and the carrier state (Figure 42–2). Half the children born to carrier women receive the X chromosome with the mutated FMR1 gene. It remains as a premutation approximately 20% of the time or increases to a full mutation (triplet repeat expansion), which causes ID. The premutation that expands to the full mutation is only transmitted by females. Females with premutations have an increased risk of ovarian failure (American College of Medical Genetics 2006). Approximately, half of females with a full mutation present with cognitive deficits such as learning disabilities, borderline intellectual functioning, and intellectual disability. Approximately 20% of the sons of carrier females with a premutation have normal intelligence and phenotype but are carriers; these sons transmit the premutation to all their daughters who, through expansion of the unstable repeats of the triplet nucleotide CGG, might produce affected children.

The physical features that are associated with fraX are more notable in boys and become more prominent with the onset of puberty. Characteristic phenotypical features include an oblong face, prominent ears and jaw, and macroorchidism. They are often restless and hyperactive and have a short attention span. Their developmental milestones, especially speech development, are delayed. Most have moderate intellectual disability, but it may be severe in others. Male carriers do not have intellectual disability. Females with fraX who have the full mutation and are symptomatic usually have learning disabilities or mild intellectual disability. Behavioral symptoms have been described in these individuals—hyperactivity and social withdrawal in about 50% and depression in about 25% (Mandel et al. 1992).

Males with fraX may present with anxiety, hyperactivity, reduced attention span, and delayed developmental milestones, particularly, in the area of speech and language skills. They also may exhibit social withdrawal with reduced eye contact, echolalia, abnormal staccato speech, stereotyped motor behavior, and unusual responses to sensory stimuli. Approximately 25–35% of children with Fragile X syndrome, however, have been noted to meet diagnostic criteria for an autism spectrum disorder (Walker and Johnson 2006).
Rett Disorder is associated with mutations in the MECP2 encoding methyl-CPG-binding protein 2 and is an X linked dominant disorders (Moldavsky et al. 2001, Amir et al. 1999). This protein is necessary in differentiation of tissues during organogenesis. Identification of this abnormality is performed by molecular genetic testing (Moeschler and Shevell 2006). Males have very rarely been identified with this disorder, as the hemizygous MECP2 gene is not compatible with life (Winneppeninkx et al. 2003). The DSM-IV-TR currently includes Rett Disorders as one of the Pervasive Developmental Disorders (PDD). Girls with this disorder generally exhibit normal early development and head circumference. Between, approximately, 5 and 48 months of age, there is deceleration of head growth. Communication and social interaction may be affected and there also stereotypical hand movements that are symmetrical, midline, and prevent the purposeful use of the hands. Other symptoms include ataxia, tremor, poorly coordinated gait, bruxism, hyperventilation, spasticity, and seizure disorder. The deterioration is initially rapid although later plateaus. Thirty families with more than one affected female have been studied. In only five of such multiplex families the MECP2 mutation was seen and other mutations that were found were “nonsense” or “missense” suggesting a different mechanism (Webb and Latif 2001). In this group also a few boys were seen with atypical milder symptoms.

Mitochondrial

Much has been learned in recent years about mitochondrial genetics and the mutations to mitochondria DNA (mtDNA) that are responsible for a number of inherited diseases. The inheritance of these disorders is different from that seen in Mendelian genetics, as inheritance is primarily maternal (Taylor and Turnbull 2005). An example of such a disorder is Leigh syndrome, which is a progressive neurodegenerative disorder that affects the brainstem, basal ganglia, thalamus, cerebellum, and spinal cord. Leigh syndrome is genetically heterogeneous and involves abnormalities in energy metabolism. The most common defect is in oxidative phosphorylation (Online Mendelian Inheritance of Man (OMIM)). Children may present with psychomotor delay, hypotonia, seizures, and lactic acidosis (Dimaruo and Schon 2003). Stresses such as acute illnesses or anesthesia, may be associated with regression of developmental skills.

Multifactorial Intellectual Disability and Complex Disorders

The etiology of intellectual disabilities may also be complex or multifactorial, with the interaction of a number of genetic and environmental factors. Approximately, 50–75% of individuals with autism present with intellectual disability (Johnson 2006). It is considered to be a disorder that is highly heritable, although the genetics and the phenotypic presentation are felt to be very complex and heterogeneous. There is a high monozygotic twin concordance, as well as a broader developmental phenotype that is seen in families with a child with an autism spectrum disorder. Different techniques have been used to study the genetics of autism, including positional cloning, study of candidate genes, and evaluation of chromosomal abnormalities (Wassink et al. 2004).

More than half the individuals with mild intellectual disability have no other disability. Their speech development in childhood is delayed, and at school age they might be deemed as immature. Some of their first-degree relatives have a history of educational problems. A history of mental illness is also common in these families. The environmental factors and the family’s socioeconomic situation are often suboptimal. However, with improvement in medical technologies, there has been an increase in identification of biologic factors.

In a large epidemiologic study in California of individuals with intellectual disability of unknown etiology, social and biologic factors were identified as important contributing factors to the etiologies for both mild and severe intellectual disability. Low birth weight was the strongest risk factor for both mild and severe intellectual disability. An increased risk of mild and severe intellectual disability was identified for children whose mothers were of advanced age and low maternal education (Croen et al. 2001).

The Metropolitan Atlanta Developmental Disabilities Surveillance Program (MADDSP) monitored intellectual disability (mental retardation), cerebral palsy, hearing loss, vision impairment, and autism in 8-year-old children in the Atlanta metropolitan area. In this study, the prevalence of mild intellectual disability in Black males was four and three times greater in 1996 and 2000, respectively, compared to White males. The prevalence of moderate to profound intellectual disability was also higher in Black males compared to White in both years, although the differences were not as marked as in the mild intellectual disability groups (Bhasin et al. 2006). Various explanations have been put forth for the differences in mild intellectual disability, including prenatal factors such as diabetes, sickle cell anemia, and others. Socioeconomic factors that impact results of cognitive testing have also been noted.

Historically, the probability of identifying etiologic factors for individuals with severe intellectual disability has been noted to be greater than for those with mild intellectual disability. However, in a tertiary care setting, approximately half of the patients were identified as having a unifying medical diagnosis for their intellectual disability with use of an extensive algorithm for medical assessment, regardless of the level of intellectual disability. Newer tests, including FISH studies for suspected disorders, subtelomeric FISH for a high index of suspicion of nonspecific genetic disorders, karyotype microarray analyses, and other studies were used (van Karnebeek et al. 2005).

Prenatal Causes: Malformations and Malformation Syndromes of Unknown Cause

Congenital anomalies are structural malformations that are present at birth. They may be associated with multifactorial inheritance and also may be of unknown etiology. There may be a single primary anomaly affecting one structure, or a multiple malformation syndrome in which there are several observed anomalies with the same etiology. These multiple malformation syndromes may be the result of chromosomal abnormalities, single gene defects, de novo mutations, maternal conditions, intrauterine infections, toxicity of drugs or teratogens. They usually occur during organogenesis of the embryo and are seen in approximately 3% of newborns. Up to 40% of persons with intellectual disability of unknown cause have three or more major or minor anomalies.
Major malformations result from an intrinsic error in organogenesis such as cleft lip and palate. Minor malformations, or dysmorphic features such as epicantal folds and transverse palmar creases do not cause functional problems. Minor dysmorphology may serve as indicators of disturbance in organogenesis and a prenatal etiology for a child's developmental presentation. Deformation is defined as an abnormality of a body part caused by mechanical compression such as club-foot. Disruption is destruction of a previously normal structure. These should not be considered malformations because their origin is extrinsic and they usually occur later than malformations (Graham 1992).

The causation and pathogenesis of many syndromes have been identified with medical diagnostic advances, sometimes leading to changes in the classification of disorders. Although Down syndrome is associated with a number of malformations, it is now categorized as a genetic disorder (chromosomal aberrations) because of the understanding of its genetic mechanism. Angelman and Williams syndromes, formerly classified as malformation syndromes of unknown origin, are now considered microdeletions, a subgroup of genetic causation.

**Malformations of the CNS**

The development of the CNS begins at the third and fourth weeks of gestation when the neural plate twists itself into a neural tube; development and maturation continue several weeks after birth. The CNS malformations may be connected with genetic abnormalities or may be caused by external insults and are then classified accordingly.

**Neural tube defects** are examples of severe CNS malformations known to be multifactorial, with both extrinsic and genetic contributing factors. **Anencephaly** originates when the neural tube fails to close at the beginning of CNS development. This condition is associated with absence of a significant portion of brain and skull, resulting in stillborn birth or death soon thereafter. With adequate folate supplementation before conception and during the first trimester of pregnancy, 50–70% of these anomalies can be prevented. Since mandatory folate fortification of cereal grains in January 1998, there have been approximately 1340 live births with spina bifida and 840 births with anencephaly, representing a 26% decline in estimated average cumulative incidence of neural tube defects (Center for Disease Control, 2004). Before fortification in 1995–1996, the average annual spina bifida and anencephaly cases per 10,000 live births were 6.4 and 4.2, respectively, following fortification in 1999–2000, the rates were 4.1 and 3.5, respectively. Neural tube defects range from anencephaly, incompatible with life, to an asymptomatic, usually undiagnosed, occult **spina bifida. Meningomyelomencele** is a neural tube defect characterized by various neurological deficits, depending on the level of involvement of the spinal cord. It is often associated with other CNS malformations, especially hydrocephalus, which may be associated with mental retardation. However, individuals with severe disabilities associated with meningomyelocele may have intact intelligence.

**Holoprosencephaly** occurs when the forebrain fails to closure during CNS development, resulting in a single-lobed brain rather than double-lobed cerebral hemispheres. Severity of symptoms is associated with the degree of brain impairment. Holoprosencephaly is associated with mid-facial anomalies and may occur as part of other syndromes such as trisomy 13. **Microcephaly** may also be associated with chromosomal anomalies, and may have autosomal dominant, recessive, or X-linked inheritance. Microcephaly may also result from arrested brain growth caused by extrinsic factors such as prenatal and neonatal viral infections as well as intracranial hemorrhage.

Disturbances during the cell migration that occurs from 7 to 24 weeks of gestation may result in cortical gyrus anomalies—**lissencephaly** (nongyral cortex) and **pachygyria** (broad gyri). These may also be associated with chromosomal deletions. An example is the **Miller–Dieker syndrome** with multiple major and minor anomalies. Smaller areas of heterotopias are also caused by disorders in migration. Periventricular and subcortical heterotopias have been associated with seizures, and intracortical heterotopias have been noted to occur in individuals with reading disorders and schizophrenia (Chevassus-Au-Louis et al. 1998). Agenesis of the corpus callosum also may also occur from a disturbance of cell migration and may be present in a number of syndromes. Occasionally, it is also seen on neuroimaging studies of nonsymptomatic individuals. Hydrocephalus (enlargement of ventricles with increased cerebrospinal fluid volume) may be the result of an unknown malformation, but it can also have X-linked inheritance, develop in connection with meningomyelocoele, or result from pre-, neo-, or postnatal infection, tumors, and other causes.

**Malformation Syndromes of Unknown Origin**

An estimated 50% or more of the malformation syndromes have no known cause. Many of these syndromes are known by the name of their discoverer (see Table 42–5). In clinical practice, however, one often encounters malformation syndromes that have not been formally described and named, with improved genetic techniques, the cause of many of these malformations will certainly be delineated.

**External Prenatal Causes**

External prenatal causes include the deleterious effects of identifiable external factors on the developing fetus. These external prenatal causes are estimated to be responsible for 6–18% of mental retardation cases (McQueen et al. 1986, Gillberg 1997).

**Maternal Infections**

Viral infections in the mother can interfere with organogenesis, and the earlier in pregnancy they occur the more severe their effect will be, as exemplified by congenital rubella. Rubella infection during the first month of pregnancy affects the organogenesis of 50% of embryos. Infection in the third month of pregnancy disturbs the development of 15% of fetuses. Various systems are affected that may result in intellectual disability, microcephaly, hearing and vision impairment, congenital heart disease, and behavior problems. Fortunately, the incidence of congenital rubella has greatly decreased because of the availability of immunization to prevent this infection.

**Congenital cytomegalovirus (CMV)** infection may result in microcephaly, sensorineural hearing loss, and psychomotor retardation. Antibodies against cytomegalovirus are found in approximately 80% of adults. Depending on
the population, primary infections occur during 2–5% of pregnancies. CMV inclusion bodies are seen in urine specimens of newborns who were infected prenatally.

**Congenital toxoplasmosis** may result in significant problems in about 20% of infected infants (hydrocephalus, microcephaly, psychomotor retardation, visual and hearing impairment) and result in milder developmental problems later in life. Congenital toxoplasmosis may be prevented by avoiding ingestion or exposure to raw or undercooked meat, or exposure to contaminated soil or cat litter.

**Congenital human immunodeficiency virus (HIV)** infection has been recognized as being associated with abnormal neurodevelopmental outcome. HIV-positive children were found to be more apt to present with abnormal motor and cognitive outcome during the first 2½ years of life, compared to congenital HIV exposure that did not cause infection. The children were considered to have abnormal motor and cognitive development if they had 2 SD or more delays on testing using the Bayley Scale of Infant Development. Early identification of these delays is felt to be important in order to initiate aggressive antiviral treatments (Chase et al. 2000).

In a German study of 41 children born to HIV–positive mothers, neurological symptoms were described at 1–7 years of age (Schmitt et al. 1991). HIV encephalopathy was characterized by microcephaly, progressive neurological deterioration, mental retardation, cerebellar symptoms, and behavioral changes. Prophylactic intravenous immunoglobulin therapy with and without zidovudine was often able to prevent regression. Improvement was seen with zidovudine treatment.

**Toxic Substances**
The most important of the teratogenic substances is ethanol, which is the cause of FAS. The prevalence of this syndrome varies around the world. Its occurrence in industrialized countries is estimated to be about one in 1,000 newborns. The diagnosis of FAS requires that a child’s weight or height be less than the 10th percentile. The child presents with notable dysmorphology including the presence of a smooth philtrum, thin vermilion, and short palpebral fissures. In addition, when alcohol is used heavily during pregnancy, there is evidence of CNS dysfunction, including microcephy, developmental delays or functional deficits. In a milder condition, called fetal alcohol spectrum disorder only two of the three dysmorphic facial features may be present, and one other characteristic such as growth retardation or developmental problems, are seen (Riley and McGee 2005). Social environmental factors during the early years have an important role in the outcome. (Figure 42–3).

Some “prescription drugs” may have various teratogenic effects. **Fetal hydantoin syndrome** (FHS) is the result of intra-uterine exposure to hydantoin (dilantin) which has long been known as being contraindicated during pregnancy, and alternative drugs are recommended for seizure control in pregnant women.

**Toxemia of Pregnancy and Placental Insufficiency**
Intrauterine growth retardation has many causes, the most important being maternal toxemia with its consequences, ending in insult to the CNS (Figure 42–4). Prematurity may be of maternal or fetal origin. When it is connected with fetal developmental deviations, the prognosis depends on the infant’s general condition. Prematurity and especially intrauterine growth retardation predispose to many perinatal complications, which may result in insult to the CNS and developmental problems.
**Perinatal Causes**
This period refers to 1 week before birth to 4 weeks after birth.

**Infections**
During the neonatal period, the most important infection from the point of view of its developmental sequelae is herpes simplex type 2. The neonate infected during a vaginal delivery may develop encephalitis within 2 weeks. Early treatment with acyclovir may alleviate the otherwise poor outcome—microcephaly, profound mental retardation, and neurological deficits. Neonatal bacterial infections such as sepsis and meningitis, also may have long-term consequences on developmental outcome.

**Hypoxia and Ischemia**
Hypoxemia and reduced cerebral blood flow may result in hypoxic-ischemic encephalopathy (HIE). The degree of impairment depends on the severity of the insult and the amount of resultant damage from reperfusion. Cerebrovascular events occur in term infants approximately 1 in 4000 term births, yet occur with greater frequency in the preterm infant (Alix 2006). Overall, severe HIE affects 2–4 per 1000 live births, with a 50–75% mortality rate (Raju 2006). Ischemic injury to the developing white matter, particularly in premature infants, has been associated with damage to the periventricular white matter. Periventricular leukomalacia (PVL) occurs in 4–26% of premature infants in neonatal intensive care units, and frequently is associated with cerebral palsy, cognitive and visual impairment. PVL may occur because of ischemia/reperfusion injury or due to cytokine-induced damage after fetal or maternal infection (Zach 2006).

Neurological symptoms during the neonatal period have a strong association with prenatal developmental deviation, later neurological integrity, and intellectual level. For these reasons, infants with perinatal problems need a thorough examination for dysmorphic features and close follow-up because multiple disabilities might become evident later in life.

**Other Perinatal Problems**
ROP (formerly referred to as retrolental fibroplasia) is a potentially blinding eye disorder that primarily affects premature infants weighing about 2½ pounds or less, born before 31 weeks of gestation. There are 14,000–16,000 annual births in the US affected by ROP. More than 90% of them are in the mild category and improve without medical treatment. About 1,100–1,500 infants require treatment and about 400–600 infants in the US become legally blind from ROP. The incidence of ROP was much more common when premature infants were routinely given 100% oxygen. However, since 1954, reduction of the level of oxygen and better methods of control of oxygen level administered to premature infants has reduced the incidence of ROP. Today, with smaller and more premature infants being saved, ROP remains as a major cause of blindness in childhood. ROP is often associated with other CNS damage, intellectual and other developmental problems. Besides the fragility of retinal vessels that can cause blindness, extremely low birth weight infants are also at risk for intracranial hemorrhage, as well as hypoglycemia resulting from a lack of hepatic glycogen storage. These neonatal problems may have results similar to those of asphyxia. Hyperbilirubinemia may result from increased destruction of red cells (e.g., hemolysis due to maternal–child blood group incompatibility) or decreased excretion of bilirubin (e.g., due to an immaturity of liver function). High level of bilirubin may result in kernicterus and may be associated with cerebral palsy, sensorineural hearing loss, and intellectual disability.

**Postnatal Causes**

**Infections**
Bacterial and viral infections of the brain during childhood may cause meningitis and encephalitis and result in significant neurological sequelae. The number of these complications has decreased because of improved treatment and the availability of immunizations such has been seen in the case of the Haemopholis influenza (Hib) vaccine.

**Toxic Substances**
Lead poisoning is still an important cause of intellectual disability in the US. The most frequent source of lead is pica—ingestion of flaking old lead-based paint. Other sources of lead have been certain fruit tree sprays, some glazed pottery, and fumes from burning automobile batteries. In 1995, leaded fuel accounted for only 0.6% of total gasoline sales in the United States. On January 1, Clean Air Act banned all sale of leaded gasoline for use in on-road vehicles. Therefore leaded gasoline is no longer considered to be a major source of lead poisoning in the Unites States, although it remains a significant contributor in developing countries. Gastrointestinal symptoms dominate in acute poisoning. Headache may be associated with increased intracranial pressure, which may even lead to coma. Late manifestations include developmental delays and intellectual disability, ataxia, seizures, and personality changes.

Among childhood malignancies, brain tumors are second in frequency after leukemia. Of these, 70–80 are gliomas, symptoms of which depend primarily on the location of the tumor. Some tumors are benign and treatable, although most have deleterious effects resulting in various neuropsychiatric symptoms depending on their location and extent. In addition, treatment such as surgery and radiation might affect the integrity and function of the brain. Other chronic illnesses in childhood such as congenital heart disease, diabetes and asthma, and/or the effects of the treatment protocols, have been noted to potentially have both short- and long-term effects on the CNS either directly or indirectly through other systems such as immunologic, hematologic, vascular, and pulmonary. As a result, developmental outcome may be affected based on the intensity, duration, and timing of these insults (Armstrong 2006). Traffic accidents, drowning, and other traumas are the most common causes of death during childhood, and are responsible for intellectual and developmental disabilities in survivors. Near-drowning is often devastating, although improvement of functional capacity may be achieved in some situations by rehabilitation because of the ability of the developing brain to recover.

**Psychosocial Problems**
The developmental level of a growing individual depends on the integrity of the CNS and on environmental and
psychological factors. The importance of environmental stimulation for child development has been appreciated since research on children in institutions showed that development was severely affected in an environment with emotional deprivation, even if there was adequate physical care. Poverty predisposes the child to many developmental risks such as teenage pregnancies, malnutrition, abuse, poor medical care, and deprivation. Severe maternal mental illness is another risk factor for developmental and behavioral problems. Mothers with severe and chronic illness might have difficulty in providing adequate care and stimulation. Children of mothers who have serious mental illness (SMI) including schizophrenia are at risk for the development of cognitive deficits, which may not be secondary to maternal illness but may represent a genetically determined predisposition to schizophrenia. Psychotic illness in a child has also been shown to be associated with a decline in cognitive abilities.

Unknown Causes
There is much variation in the report of unknown etiology for intellectual disability, due to epidemiologic challenges related to reliable classification systems, populations studied, and methods of assessment (Leonard and Wen 2002). When a unifying medical diagnosis or etiology cannot be found, it is usually assumed that the developmental presentation was prenatally determined. Severe intellectual disability has been noted to have identifiable causes in 45–80% of the time, with biological causes identified in less than half of those with mild intellectual disability (Roberts et al. 2004). No etiologies were identified for severe intellectual disability in 22% by Stromme and Hagberg (2000), 49% individuals by Cans et al. (1999), and 65% by Croen et al. (2001). In some studies, no differences were found between the severe and mild intellectual disability groups in the ability to identify an etiology. van Karnebeek et al. (2005) was able to identify etiologies in half of the children evaluated in a tertiary care center, regardless of level of cognitive functioning.

Biomedical Etiological Assessment of Intellectual Disability
Biomedical causes of intellectual disability have their origin in genetic or external factors or injury causing structural or functional disturbances of the CNS. The structural changes may or may not be recognizable by available clinical neuroimaging techniques such as CT, MRI, PET, and single-photon emission computed tomography. Newer advances using laser scanning methods have provided a way to better understand events that occur during brain development on a cellular level during neurogenesis, cell migration, and synaptic connections (Haydar 2005). As medical technology becomes more sophisticated, it is hoped that it will be possible to recognize the biological causes in an increasing number of individuals with intellectual disability.

Intellectual disability associated with syndromes and disorders with obvious phenotypical features is usually recognized earliest such as in the case of Down syndrome. The diagnosis is then confirmed by chromosomal or other appropriate laboratory studies. If there was a suspicion of a family’s risk for a genetic disorder before the birth (such as through prior genetic counseling), appropriate studies are performed in the neonatal period. Some cases of congenital intellectual disability (e.g., PKU) are discovered in the course of routine neonatal screening. Newborns with perinatal risk factors like prematurity and asphyxia should be followed up closely for later manifestations of developmental delay. Other children might come to medical attention because of a delay in achieving developmental milestones or regression in a previously normal developmental pattern. Finally, many children with milder intellectual disability will be referred for diagnostic assessment when they reach school age because of failure in academic learning.

Elements of Biomedical Assessment
First Stage Work-Up. The medical evaluation of a child with intellectual disability is performed in order to determine potential etiologic factors and a unifying medical diagnosis. This assessment needs to be performed in a systematic fashion, beginning with a thorough history and physical examination to guide the medical workup. Identifying a cause provides diagnostic clarification to medical providers and families, prognostic information, and recurrence risk information.

The scheme for assessing the etiology of intellectual disability is summarized in Figure 42–5. At any point in which a genetic diagnosis is made, consideration should be given to referral to a geneticist to guide subsequent medical assessments and provide genetic counseling to the family.

History. A detailed history includes prenatal factors such as difficulties with conception, maternal illness, premature labor, medication, bleeding and other medical problems during the pregnancy. Birth history needs to review problems with labor and delivery that may impact developmental outcome such as fetal distress, abruptio placenta, and hypoxia. Weight, length, and head circumference at birth must be assessed, particularly with relationship to the gestational age, and provide information regarding potential issues such as intrauterine growth retardation. Neonatal problems such as respiratory distress, infection, and seizures, should be noted. Medical history should include review of illnesses, injuries, and surgeries. The rate of recovery from illnesses and identification of associated episodes of regression of developmental skills need to be explored as a screen for metabolic disorders. Information also needs to be obtained regarding nutrition and feeding issues, elimination and sleep problems, medications, immunizations, as well as a complete review of systems. Developmental history should include inquiry about the various developmental domains, including receptive and expressive language, gross and fine motor skills, play and social abilities, self-help abilities. In addition to milestones, it is important to determine the rate of acquisition of skills and the developmental trajectory such as steady slow progress, an apparent reduced rate of developmental gains or plateau, or loss of skills. This type of information may indicate etiologic factors for the intellectual disability. The family history should include a three-generation pedigree, especially occurrence in the family of similar cases, developmental and learning disorders, congenital anomalies, mental disorders, multiple miscarriages, and consanguinity. A social history is also obtained to evaluate environmental and psychosocial factors that may contribute to developmental outcome.
**Physical Examination.** The physical examination should focus on searching for phenotypical manifestations of syndromes associated with ID, or other physical features suggestive of etiologic factors. It should include evaluation of growth parameters, including height, weight, and head circumference. Height and head circumference should be proportional; situations may occur in which head circumference is significantly large or small relative to height. Body mass index should be reviewed to identify failure to thrive or obesity. Phenotypical and dysmorphic features should be identified as indicators for prenatal influences. The general physical examination should closely evaluate skin for evidence of neurocutaneous lesions. Middle ear effusions, corneal opacities, and low oromotor tone should be noted. Evaluation of the neck should rule out the presence of thyroid abnormalities and findings suggestive of a syndrome such as a webbed neck. Cardiopulmonary abnormalities need to be identified. Hepatosplenomegaly is sometimes seen in storage and other metabolic diseases. Lumbosacral dimples or tufts may be present in subtle neural tube defects. Neurological examination should evaluate a child’s responsiveness to his or her environment, social

---

**Figure 42-5** Diagnostic approach to intellectual disabilities.
interaction, and language skills. Cranial nerve abnormalities should be identified, as should abnormalities in muscle mass, tone, strength, movement patterns, and reflexes. Emphasis should be placed on motor and reflex asymmetries. The presence of an abnormal neurological exam should guide the decision to obtain imaging studies of the brain and spinal cord.

**Diagnostic Studies.** Upon completion of the history and physical examination, a working hypothesis for the etiology for the intellectual disability is often obtained and will guide the medical workup. Hearing testing should be done on every child with a language delay, and vision should be evaluated to rule out refractive, metabolic, certain neurological and other disorders. In addition to previously mentioned history taking and physical examination, the following: banded karyotype and fragile X studies by DNA method for both males and females with unexplained ID. Banding should occur at least at the 500 G level, with some centers providing high resolution karyotype (≥ 650 bands) (Walker and Johnson 2006, Roberts et al. 2004, Moeschler and Shevell 2006). These studies are essential if the family history is positive or if the physical and behavioral phenotype are without major findings. Metabolic studies and blood chemistries may need to be considered in the context of a history of regression of developmental skills, organomegaly, distinct feature suggestive of a particular genetic syndrome (e.g., mucopolysaccharidosis), in certain instances of sensorineural hearing loss and/or migraine. Magnetic resonance spectroscopy may also be used to further delineate certain metabolic disorders. Failure to thrive and poor growth may be associated with some metabolic, chromosomal, endocrine, CNS, and gastrointestinal disorder, as well as nutritional and psychosocial factors, requiring an evaluation consistent with the presenting features. Lead screening should be done on every child, particularly in the child with developmental delays, hyperactivity, and atypical features. Neuroimaging, preferably MRI, is to be performed if the patient has neurological symptoms, cranial abnormalities, microcephaly, or macrocephaly (Curry et al. 1997). CT scans are often used when evaluating osseous structures of lesions. Neurophysiologic testing such as routine or long-term monitoring electroencephalogram (EEG), should be considered for behaviors suggestive of seizures, staring episodes, paroxysmal outbursts without known precipitants, developmental regression, or a high index of suspicion for a seizure disorder despite a prior normal EEG.

After this basic workup, the probable cause or at least timing of the injury should become apparent, thus allowing discussion with the family concerning possible inheritance. If there are significant congenital anomalies, more than three dysmorphic features, a high index of suspicion, or positive results from genetic studies, consultation with a geneticist should be sought. If there is a suspicion of a progressive neurological disorder, consultations with a neurologist are needed, as well as a geneticist and a neurological ophthalmologist. In certain situations, biopsies of muscle, skin, or other tissues are helpful.

**Prenatal Diagnosis.** Prenatal diagnostic methods are increasingly available. Amniocentesis is useful in diagnosing chromosomal and metabolic disorders; chorionic villus sampling (CVS) is used for chromosomal and molecular genetic studies. Amniocentesis or CVS with chromosomal studies are usually recommended for women 35 years or older. Prenatal diagnostic studies should be made available to everyone requesting them and should be used if there is a known risk for a genetic or congenital problem. Even if the parents do not plan a therapeutic abortion, if the results are positive for a certain disorder, they will be able to prepare for the birth of a child with special needs and to marshal supports. The American College of Obstetrics and Gynecology has provided new recommendations for screening of all pregnant women for Down syndrome, regardless of age. The screening recommendations include an ultrasound that evaluates the thickness of the back of the neck of the fetus, nuchal translucency, blood test to measure pregnancy-associated plasma protein A (PAPP-A) and human chorionic gonadotropin (hCG) in the first trimester. Those with positive findings are then offered genetic counseling and CVS or mid-trimester amniocentesis. Neural tube defect screening done by evaluating the level of alpha-fetoprotein (AFP) should be offered in the mid-trimester to those women who elect only first-trimester screening for Down syndrome (American College of Obstetrics and Gynecology 2007). AFP, hCG, unconjugated estriol (uE3), and Inhibin-A may also be performed in the mid-trimester to assist in the screening for Down syndrome.

Ultrasound of the fetus to evaluate for major malformations is often performed at approximately the 20th week of gestation. Carrier screening, which is increasingly available for certain recessive disorders, should be offered to all persons in high-risk populations such as Ashkenazi Jews for Tay–Sachs disease. Careful counseling is necessary to help the prospective parents decide on all available options if they are found to be positive for the particular trait.

**Differential Diagnosis of Intellectual Disability**

The diagnosis of intellectual disability itself should be relatively straightforward as it reflects the current level of intellectual and adaptive functioning. Some persons with learning disorders or communication disorders might appear to have low level of functioning, but appropriate psychological and communication testing will demonstrate that their impairment is in the development of specific skills and is not generalized. Dementia can be diagnosed at any age, whereas intellectual disability is diagnosed only if the onset is before age 18 years. However, both disorders might be diagnosed in persons younger than age 18 (see discussion of mental disorders due to a general medical condition further on). It is often asked how one differentiates between intellectual disability and autistic disorder. Actually, such a question is erroneous because these disorders are not mutually exclusive; in fact, most persons with autism also have intellectual disability. An uncomplicated intellectual disability is not associated with qualitative impairment in social interaction and communication, which is diagnostic of autistic disorder.

**Course and Natural History of Intellectual Disability**

The development of an individual with intellectual disability depends on the type and extent of the underlying
disorder, associated disabilities and disorders, environmental factors, such as general health, education, treatment, and other services), and psychological factors (cognitive abilities, comorbid psychopathological conditions). Some general principles concerning the developmental trajectories of various intellectual disability–associated disorders and syndromes are seen in Figure 42–6.

Life expectancy depends on a number of factors already discussed. Persons with profound intellectual disability with associated multiple disabilities and an inability to ambulate or self-feed have a much shorter life expectancy according to an extensive study conducted in California (Eyman et al. 1990).

When the patient is a person with intellectual disability, even ordinary ailments may be difficult to diagnose (and may become life-threatening) as the person may be unable to describe the complaints because of communication difficulties. Physical pain and other discomforts are often communicated by these individuals through their behavior such as aggression or SIB, leading to a psychiatric referral while the physical disorder remains undiagnosed. Many syndromes predispose the person to certain health problems that have to be anticipated. Illnesses typical of Down syndrome have been discussed earlier. Nonambulatory persons are at risk for both respiratory and urinary tract infections. Gastroesophageal reflux is common and often leads to aspiration and anemia.

**Habilitation and Treatment Approaches to Intellectual Disability**

**Evolution of Attitudes to Persons with Intellectual Disability**

The information that has survived from ancient times on the treatment of persons with intellectual disability refers primarily to those with external physical abnormalities which

---

**Figure 42–6** Schematic representation of patterns of developmental disorders (arrows refer to the point of insult): (a) normal developmental course; (b) fixed, nonprogressive type of developmental disorder; (c) metabolic type of disorder of development in which the manifestations of the underlying process (e.g., Tay–Sachs disease) occur after birth and evolve into a progressively deteriorating course; (d) acquired developmental disorder: the curve represents normal development up to a point of insult (arrow) to the CNS; (e) environmental disorder of development: a fluctuating course, with periods of stress (downward arrows) and periods of nurturance or positive intervention, or both (upward arrows); (f) outcomes: the convergence (arrow) of the various developmental courses represents the point at which the physician becomes aware of the developmental disorder (Source: Szymanski et al. 1989, Mental retardation. In American Psychiatric Press Review of Psychiatry, Vol. 8, Tasman A, Hales RE, and Frances AJ (eds). American Psychiatric Press, Washington, DC, USA, p. 227).
might have been associated with intellectual disability. In antiquity, the attitudes toward people with disabilities included rejection, as well as protection (review, Berkson 2004). Persons with mild intellectual disability and without external deformities were probably accommodated in productive tasks in primitive agriculture and industry. In some cultures such as in Sparta and Rome, infants with deformities were not permitted to live. Aristotle, in *Politics*, stated that there should be a law that deformed children should not be permitted to live (Scheerenberger 1983). In those early periods intellectual disability was probably not differentiated from mental illness. The Jewish, Moslem, and early Christian traditions included people with disabilities among those who should be given care and protection (Scheerenberger 1983). Leviticus 19:14 forbids cursing the deaf or placing obstacles before the blind (Berkson 2004). The Talmud listed three types of persons with limited capacity: deaf persons, minors and “shoteh” (person with intellectual disability or with mental illness). Interestingly, it described how the “shoteh” could function according to society’s expectations. For example, he could perform ritual slaughter if was supervised by a non-shoteh. Thus, the focus was on how such individuals could be integrated within the community (Lifshitz and Merrick 2001). In John 9, Jesus states that one’s blindness was not a punishment for sinning. The Quran (Surah IV, v. 5) calls for helping the “weak of understanding” (Berkson 2004). Still, it was unclear to what degree there was differentiation between mental illness and intellectual disability. In Roman writings terms “amens” and “demens” were used which were interpreted as referring to intellectual disability and mental illness, respectively (discussion in Berkson 2006). In the middle age, however, individuals with disabilities were gradually assumed to be a product of sin—often of the sexual union of a woman with the devil—and possessed by demons. In his writings, Martin Luther described a child with intellectual disability whom he saw as a changeling who should have been drowned (Scheerenberger 1983). Some towns cared for persons with intellectual disability or mental illness in orphanages, poorhouses, or in a humane manner in the equivalent of foster homes such as in Geel, Belgium. Many abandoned children with intellectual disability were placed in hospitals where they had little chance of surviving.

The modern care of persons with mental disorders, initiated at the end of the 18th century by Philippe Pinel in Paris, also affected the care of persons with intellectual disability. His focus was on “moral” management (gentle and humane care, education, recreation), rather than on inducing obedience (Scheerenberger 1983). Paradoxically, in our times, there are still some who focus primarily on “behavioral control” of persons with intellectual disability, even by means of aversive behavioral modification. Itard, a student of Pinel, in his work with Victor, the “Wild Boy of Aveyron” (an abandoned, possibly autistic child), laid the foundation for the development of special education. Another of Pinel’s students, Edouard Seguin, devoted his professional life to the study and treatment of intellectual disability. His work formed the basis of the enlightened and educational approach to the care of persons with intellectual disability and to the change of institutions from custodial asylums to education-oriented schools.

In the colonial era, the American approach to intellectual disability followed that of England. Persons with intellectual disability together with persons with mental illness were kept in poorhouses or “farmed out” at public expense to the lowest bidder. Toward the middle of the century, developments in Europe started to influence the approach to intellectual disability in the US. The ideas of Seguin were the basis for the earliest school for children with intellectual disability in the US, which was established in 1847 by HP Wilbur in Barre, Massachusetts. In 1848, Seguin emigrated to the US and was instrumental in the development of a number of special schools, as well as in founding (with six other physicians) the Association of the Officers of the American Institutions for Feeble Minded (the predecessor of the American Association of Mental Retardation and currently the American Association on Intellectual and Developmental Disabilities) in 1876. Seguin viewed the mission of the residential facility as educating children with intellectual disability (who could not be accommodated in schools in the community) and then returning them to their families. He advocated small institutions located in the students’ communities as well as provision of services to children living with their families (Scheerenberger 1983).

The first state-funded residential school was founded in Massachusetts by Samuel Gridley Howe, at first as a division of a school for the blind in 1848 and as a separate institution in 1855. Almost from the beginning, Howe was against inhumane treatment of persons with intellectual disability, stating in an 1869 report to the Governor of Massachusetts: “it would be demonstrated that no idiot need be confined or restrained by force...” Within the next 25 years, there were 15 public institutions (Scheerenberger 1983). At first they followed the precepts of Sequin’s “moral treatment,” but later they changed, reflecting developments in medicine and in society’s perception of intellectual disability. Several factors contributed to this (Donaldson and Menolascino 1977). Developments in neurology led to a more pessimistic view of intellectual disability as being due to an incurable brain defect. Genealogical studies led to a mistaken belief that intellectual disability was hereditary and associated with criminality and other social maladjustment. This was later reinforced with the introduction of intelligence testing, which “discovered” a high prevalence of persons with mild intellectual disability (termed morons) among socially maladjusted persons (probably resulting from poverty and lack of education rather than intellectual disability). Finally, with the introduction of psychoanalytic theories, psychiatrists became less interested in persons with intellectual disability who were seen as unable to benefit from dynamically oriented psychotherapy. As a result, institutions shifted from educating persons with intellectual disability and protecting them from abuse to protecting the society from them. The period that followed up to the first half of the 20th century, the “tragic interlude,” witnessed the building of large institutions (although no more than 10% of persons with intellectual disability were institutionalized at one time), the introduction of laws on involuntary sterilization, and segregated special education (Donaldson and Menolascino 1977).

A number of developments led to the next period, culminating in the current recognition of the rights of persons with intellectual disability to services and inclusion in society. Research on the effects of attachment and deprivation resulting from institutionalization documented the environmental factors in the genesis of intellectual disability, as
as well as the salutary effect of a stimulating environment and
education (Skeels and Dye 1942). In fact, it was a sort of a
dejà vu of the work of Itard and Sequin. The work of a par-
ents’ organization (National Association for Retarded Cit-
zens, currently known as The ARC) contributed to a gradu-
al improvement in institutions, to deinstitutionalization,
and to community-based care. The US Supreme Court 1954
decision in Brown v. Board of Education ending racial segre-
gation in schools, and the civil rights movement in general,
sent the message that all kinds of segregation—educational
and otherwise—were wrong. Many important lawsuits on
behalf of persons with mental disabilities followed and the
most relevant are summarized in Table 42–6, and important
statutory developments in Table 42–7.

Education of Children with Intellectual Disability

Laws providing for educational opportunities for children
with disabilities have evolved in the United States over the
years, since 1896, when the first successful special class
for children with intellectual disability was established in
Providence, RI (Sarason and Doris 1975). Such classes were
commonly self-contained and separate, frequently housed
in separate buildings. Starting with early nineteen-seventies,
the concept of educational placement in a least restrictive
alternative was introduced and codified in legislation. In
1972, Massachusetts adopted a special education law; the
current Chapter 71B—Chapter 766 of the Acts of 1972—
guaranteeing public education and all necessary services to
all children of 3–22 years of age; placement is according
to service needs rather than diagnostic labeling, interdis-
ciplinary core assessment with parents’ participation, and
an educational plan specifying goals to be achieved. The

parents have the right to reject the plan and appeal it. The
federal PL 94-142 of 1975 was modeled on Chapter 766.
Originally the term “mainstreaming” was used, later
supplanted by “inclusion.” The norm now is that the over-
whelming majority of intellectually disabled children can
be educated jointly with nondisabled ones, in “integrated”
classrooms, if provided with appropriate educational and
other supports and therapies (such as special education
teachers and aides, modified curriculum, language therapy).
However, even with intensive supports some children are still
educated in separate classes, usually because they require
very structured settings and/or have major behavior man-
gement needs. If a child’s needs cannot be provided for in
the public schools, the local school systems have an option
(with parent’s consent) to place the child on public expense
in a special private school (day or residential).

The outcomes of separate–special vs. inclusive edu-
cation are still studied. In their review of relevant studies,
Lipsky and Gartner 1997 found that the special needs stu-
dents included in regular classes did better academically and
even if the difference was not marked, the inclusive place-
ment was more liked by the parents and educators and was
cost-effective. The social and behavioral outcomes were also
favorable, ascribed to factors such as using nondisabled
peers as role models, availability of friendship networks, and
of social contacts. On the other hand, students in inclusive
placements may still experience significant stigma (Cooney
et al. 2006).

Right to free and appropriate public education (FAPE)
is currently guaranteed to all children and youth in the
United States by federal law. It was first introduced as the

</table>

Another important development in the habilitation of persons with intellectual disability has been the Americans with Disabilities Act (ADA), first adopted in 1990 and periodically revised since. The ADA prohibits discrimination on the basis of disability in employment, government, public accommodations, transportation, and telecommunications. A disability is defined as a physical or mental impairment that substantially limits one or more major life activities. Title I of ADA requires employers with 15 or more employees to provide individuals with disabilities with equal opportunities and to make reasonable accommodation for them if they are otherwise qualified. Title II requires that State and local governments give people with disabilities an equal opportunity to benefit from all of their programs, services, and activities (and provide architectural and other accommodations necessary to that end such as access). Title III covers businesses and nonprofit service providers. They must comply with basic nondiscrimination requirements that prohibit exclusion, segregation, and unequal treatment. Title IV addresses telephone and television access for people with hearing and speech disabilities.

Another important piece of legislation has been the Civil Rights of Institutionalized Persons Act (CRIPA) of 1990, which authorizes the US Attorney General to investigate conditions of confinement at State and local government institutions including correctional facilities, and institutions for people with psychiatric or developmental disabilities. Over the years numerous institutions for persons with intellectual disability were investigated and conditions in them were markedly improved through court orders or court approved settlements. One of the most common findings has been poor mental health care in these facilities, including inappropriate use of psychotropic drugs (Source: U.S. Department of Justice; http://www.ada.gov/cguide.pdf).

**Overall Goals of Treatment of Persons with Intellectual Disability**

Intellectual disability is a functional disability: thus, the goal of treatment is reduction or elimination of the disability. There are three aspects to the treatment:

1. Treatment of the underlying disorder that is causative of intellectual disability, for example, PKU
2. Treatment of the comorbid disorders that add to the functional disability physically or mentally
3. Interventions targeted at the functional disability of the intellectual disability itself: educational, habilitative and supportive approaches depending on the person’s individualized needs

**Overall Principles of Treatment of Persons with Intellectual Disability**

The current approach to the services for persons with intellectual disability is based on the following principles:

1. Treatment of the underlying disorder that is causative of intellectual disability, for example, PKU
2. Treatment of the comorbid disorders that add to the functional disability physically or mentally
3. Interventions targeted at the functional disability of the intellectual disability itself: educational, habilitative and supportive approaches depending on the person’s individualized needs
• Normalization principle (Nirje 1969). This refers to “making available to the mentally retarded patterns and conditions of everyday life that are as close as possible to the norms and patterns of the mainstream of society.” This has largely evolved into the principle of inclusion, which is usually interpreted as an active effort to include persons with intellectual disability in all normal aspects and opportunities of society’s life, through providing them with supports necessary for success. An excellent description of inclusion is as follows: “Inclusion means that all people, regardless of their abilities, disabilities, or health care needs, have the right to: be respected and appreciated as valuable members of their communities; participate in recreational activities in neighborhood settings; work at jobs in the community that pay a competitive wage and have careers that use their capacities to the fullest; and attend general education classes with peers from preschool through college and continuing education.” (Source: Institute for Community Inclusion, Children’s Hospital, Boston: http://www.communityinclusion.org/doc.php?doc_id=1&type=project&id=40)

• The ultimate goal is to eventually end segregated services and education and provide persons with intellectual disability with the necessary specialized support services in regular educational, living, and work settings.

• Right to community living. This confers the right to live with a family, preferably one’s own or a substitute one if necessary (foster or adoptive). This includes moving individuals living in large residential facilities to as normal a setting as possible, for example, community residences, supervised apartments, and foster homes. Furthermore, children as well as adult are not to be institutionalized regardless of the level of disability. However, some children are still placed in special residential schools (usually private) for specific reasons, typically medical or behavioral needs that require specialized treatment. Historically, the majority of persons with intellectual disability lived at home and no more than 10% were in institutions at any point. However, institutions played a disproportionate role in attitudes to their care. At their peak in 1967, there were 194,650 persons living in them: this number dropped to 41,653 in 2004 (Prouty et al. 2005). Data from the National Health Interview Survey on Disability and the Residential Information Systems Project indicate that an estimated 92% of all Americans with ID/DD live with family members, spouses or alone; 6% live in community-supported living arrangements; 1% live in large institutions; 1% live in nursing homes. Between 1960 and 2004, 176 of large state institutions or units for people with intellectual disability were closed. By 2004, ten states closed all their institutions. In contrast, the number of persons living in small (less than six persons) residences in the community between 1977 and 2002 increased 12-fold, from 20,184 to 263,415 (1205%). The number of children and youth in large state institutions decreased from over 91,000 in 1964 (47.6% of all residents) to 1600 (4%) in 2004. One-third of the states have eliminated admission of children and youth altogether (Schultz et al. 2005).

• Employment of adults in the community according to their abilities. This is an important aspect of inclusion. The current trend is to employ them in competitive job markets with supports such as vocational training and supports by job coaches. However, many individuals, especially with severe degrees of disability, are still placed in sheltered workshops or occupational–recreational day programs.

• Use of normal community services and facilities. This includes activities such as shopping, banking, transportation, recreation) through training and ongoing supports.

• Advocacy and appropriate protective measures. This ensures protections against inappropriate use of pharmacological and behavioral measures as substitutes for active education and treatment, inclusion in research programs without proper, truly informed consent, and general exploitation and abuse.

Prevention of Intellectual Disability

Primary Prevention
The goal of primary prevention is to prevent intellectual disability from arising in the first place. To be effective, it should encompass medical, public health, educational, and other measures. Examples include, immunizations to prevent congenital rubella, measles (encephalitis), and Rh mother–child incompatibility; measures to prevent lead poisoning and teenage pregnancies; provision of prenatal vitamin supplementation (to prevent neural tube defects); better neonatal care; measures to prevent substance abuse in pregnancy and childhood trauma (e.g., the use of infant car seats), and early intervention and enrichment programs for children at psychosocial risk. It is a question of personal values whether prenatal diagnosis and elective termination of pregnancy (e.g., if Down syndrome is found) would be called primary prevention, as childbirth rather than the disorder is prevented.

Secondary Prevention
Secondary prevention includes measures to recognize conditions that can lead to intellectual disability as early as possible and to treat them to prevent the disability. Examples include the early diagnosis and treatment of PKU, and other metabolic conditions and congenital hypothyroidism.

Tertiary Prevention
Tertiary prevention could be called habilitation as well (Rowitz 1986) because it aims to attain a functional level that is as good as possible in the presence of intellectual disability. It includes both biomedical and sociocultural measures such as early intervention for disabled infants, proper education, multifaceted family support, and prevention or early treatment of comorbid disorders that could reduce functioning, both medical and mental.

Prevention of Psychosocial Dysfunction
An essential part of tertiary prevention consists of preventing psychosocial dysfunction because mental disorders are an important cause of maladaptation in persons with intellectual disability (Szymanski 1987). This category can also be subdivided. Primary prevention includes proper education and employment and opportunities to achieve in life so that the person can develop a sense of self-worth and self-esteem;
training in social skills and sexuality; and provision of appropriate social supports and recreation. Secondary prevention includes early diagnosis and treatment of emerging mental disorders rather than a focus on behavioral crisis intervention only. Tertiary prevention includes good psychiatric care and habilitation as well as a proper milieu when a person has a chronic mental illness (including substance abuse) that requires continuous care. In all situations prevention has to include measures directed both at the person and at the environment (caregivers, services, public policies).

MENTAL DISORDERS IN PERSONS WITH INTELLECTUAL DISABILITY

Although at the advent of psychiatry, intellectual disability had been considered as an important and integral province of psychiatry, starting in the early part of the 20th century, there was a loss of interest in persons with intellectual disability largely in part due to emergence of psychoanalysis with its predominant focus on communication involving prerequisite development of good language skills and cognitive abilities. In the late 1970s interest revived in this branch of psychiatry, termed “neurodevelopmental neuropsychiatry” (Harris 1995 2006). Nevertheless, unlike in the United Kingdom and Australia there has not been a systematic emphasis on training of psychiatrists in neurodevelopmental psychiatry in the US, especially in terms of mental health care of adults with intellectual disability.

The same mental disorders occur in persons with intellectual disability as in those without intellectual disability: thus, the discussion of definition, etiology, pathophysiology, natural history of specific mental disorders, described elsewhere in other chapters of this textbook, applies here as well. This section focuses only on those aspects of mental disorders that might be modified by the presence of intellectual disability.

Prevalence of Psychopathology in Persons with Intellectual Disability

Accurate assessment of prevalence of mental disorders in persons with intellectual disability is difficult, for a number of reasons (Dykens 2000, Kerker et al. 2004). First, one common problem is the selection of representative samples of persons with intellectual disability in studies involving the general population. Many earlier studies focused on persons living in large residential institutions which resulted in an overestimation of the prevalence of emotional and behavioral disorders since these disorders were a common reason for institutionalization. Conversely, other studies involving select community samples excluded institutionalized individuals. Studies of referred individuals in mental health clinics have also tended to be biased as a common reason for referral involves emotional and behavioral concerns. In turn, studies involving unselected populations such as those of persons receiving services through community-based programs have tended to miss individuals not able to attend such programs (or have not been accepted by them), often because of behavior problems. Second, the assessment of persons with intellectual disability has also varied from detailed evaluation by means of psychological and developmental tests, inappropriate use of such tests, or lack of development of structured or semi-structured measures to assess them. Inconsistent use of diagnostic criteria of mental disorders, particularly before the publication of the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) (American Psychiatric Association 1980), was commonplace. Many studies then did not use standard diagnoses in persons with intellectual disability and referring to these disorders in general terms such as “psychiatric illness,” “mental health condition,” “behavior disorder” (Kerker et al. 2004). Methods of diagnosis have also differed. In summary therefore, diagnosis of mental disorders in this population has remained difficult, particularly for clinicians untrained and inexperienced with persons with intellectual disability (American Psychiatric Association 1991). Third, an important obstacle to accurate diagnosis of comorbid mental disorders in persons with intellectual disability has been “diagnostic overshadowing”—a tendency of clinicians to overlook the true co-occurrence of mental disorders in the presence of intellectual disability (Reiss et al. 1982). This obstacle still leads to undue exclusion of persons with intellectual disability from services that may be available for other more specific diagnoses such as children with attention-deficit/hyperactivity disorder who have been recognized to have comorbidity with anxiety and affective disorders as early mid-1980s with the advent of DSM-III (Biederman et al. 1986, Munir et al. 1987). A fourth problem has been the issue of persons with intellectual disability serving as informants. Studies of persons with intellectual disability have therefore exclusively relied on clinical interviews with caregivers or on retrospective clinical records review. Some studies have used a variety of structured and semi-structured diagnostic instruments, which were designed to measure behaviors or personality features, but not necessarily to arrive at a direct categorical diagnosis of a mental disorder (see review by Dykens 2000 and Kerker et al. 2004). Finally, some large-scale studies used diagnoses included administrative and surveillance but not necessarily direct epidemiological datasets reported to state offices by various agencies, without consideration of the manner in which such diagnoses were systematically made. There have been few controlled studies of persons with intellectual disability. It is therefore not surprising that with these methodological problems there have been wide variations in the prevalence of psychopathology in persons with intellectual disability, ranging from under 30% to over 71% (Table 42–8), although most agree that it is significantly higher than in persons without intellectual disability. The representative studies are summarized in Table 42–8. Virtually all types of mental disorders have been described in persons with intellectual disability, although their reported prevalence also varies from study to study (Dykens 2000).

Despite its influential beginnings in developmental epidemiology, difficulties in measurement of mental disorders in intellectual disability, including autism spectrum disorders, had led children with intellectual disability and autism to be excluded from the proposed but subsequently abandoned national studies on Use, Need, Outcomes, and Cost of Child and Adolescent Populations (UNOC-CAP) project by NIMH. Yet, an NIMH-sponsored consensus report subsequently considered autism as one of the most reliable diagnosis in psychiatry and their exclusion was not
justified (Bristol et al. 1996). In terms of standardized “respondent-based” interviews, administered by lay interviewers, the field of developmental disabilities has continued to provide leadership. Recent advances in diagnosis of autism using the Autism Diagnostic Observational Schedule (ADOS-G) by means of activity-based observational ratings is an important more recent example (Lord et al. 1997). As diagnostic criteria for many mental disorders are behaviorally defined structured interviews remain limited by their textually defined restrictions and difficulties in semantic understanding.

### Intellectual Disability and Behavioral Patterns

#### Risk Factors for Psychopathology

A number of factors have been proposed as relevant to the increased risk of persons with intellectual disability to develop psychopathology. These have been reviewed by

*These studies included subjects with mild to severe mental retardation.

Dyken's (2000) and are summarized below. Although her paper focused on children, it is equally relevant to adults as well.

**Cognitive and Adaptive Impairments**

By definition persons with intellectual disability have reduced ability to deal with requirements and stresses of life. Even individuals who received good education and were able to develop reasonably good adaptive skills, often depend on structure and familiarity of behavioral "scripts" they were taught. They may have difficulties in adapting to changes in routine or making decisions in the face of unexpected events, and therefore may respond with anxiety. Furthermore, poor communication skills interfere with understanding explanations or instructions and with communicating own thoughts and feelings; persons with intellectual disability therefore may resort to behavioral means as a form of communication. In fact it is often observed that such behavioral responses including anxiety and aggression may abate, when an individual acquires better communication skills, or is given a more developmentally appropriate channel of expression.

**Psychological Factors**

In the past, it has been widely held that persons with intellectual disability have a limited "personality" in common. These presumed traits, often contradictory, included: passivity, aggressiveness, attention getting, shyness, talkativeness, lack of sexual drive, and hyper or hypo sexuality (Reiss 1994). However, it is now more widely held that a full spectrum of personalities can be encountered among persons with intellectual disability, as in the general population (Szymanski and Kaplan 2006). Nevertheless, persons with intellectual disability are more likely to show certain characteristics such as low self image (Szymanski and Crocker 1989) often related to their experiences of failure, perception that adults important to them (especially parents) are disappointed with them, and negative comparison between themselves and their age peers (Reiss 1994, Dykens 2000). This might be associated with an "outerdirectedness" (relying on others for self-assessment) and "learned helplessness" which is seen as associated with psychopathology such as depression.

**Environmental–Social Factors**

Despite marked progress in development of care systems and services, persons with intellectual disability continue to encounter social rejection and stigma. Much of this is related to our cultural values; in some cultural contexts the stigma being more pronounced than in others. One aspect of stigma is related to public or professional ignorance of intellectual disability, including fears that it is associated with violent behavior. Persons with intellectual disability are well aware of such negative experiences, since they now live in the community. Such psychosocial factors have been found to correlate with development of depression (Reiss and Benson 1985). Peer attitudes are of great importance in adjustment of children with intellectual disability. Much progress has been done in schools where a peer-buddy system provides social and other support to disabled children and may protect them against bullying and teasing, which is common, especially if a child has unusual phenotypical features (Dykens 2000). Persons with intellectual disability are at risk for being abused, for reasons such as being seen as easy victims and unable to defend themselves. Such inherent abuse, unknown to the caregivers, might lead to behavioral disturbance and psychopathology. Family-related factors in stigma are important as well since family support and acceptance are essential to the preservation of the affected child's progress. This requires not only love and acceptance but also promotion of the child's strengths (i.e., an appreciation of the child's abilities as well as disabilities) without putting on him or her unrealistic demands and expectations. Parental advocacy is often essential in procuring services to which the child is entitled and much depends on such parental understanding of the child's needs.

Behavioral patterns and psychopathology may also be influenced by biomedical factors. As has been shown in the early epidemiological studies by Rutter and Tizard in the Isle of Wight, persons with intellectual disability have long been known to have seizure disorder, especially if their cognitive impairment is severe. In turn, seizures may be comorbid with mental disorders (review, Dykens 2000). Blindness may be associated with CNS damage and mental retardation and congenitally blind children may exhibit behavioral patterns of consistent with co-diagnosis of autism spectrum disorders. Persons with intellectual disability also commonly have manifest comorbid medical disorders and may be in treatment with medications, which might have a range of behavioral side effects. The influence of these various factors on the functioning and behavior is depicted in Figure 42–7.

**Behavioral Phenotypes**

Association of behavioral/personality traits with certain conditions underlying intellectual disability has long been noted. For example, persons with Down syndrome are often deemed to be overtly friendly, social, “prince charming” types, but these features have also been explained as a result of others’ accepting and perhaps infantilizing attitudes towards them. With progress in genetics, the concept of “behavioral phenotypes,” first introduced by Nyhan in 1972, has now gained popularity. Dykens has defined behavioral phenotypes as “the heightened probability or likelihood that people with a given syndrome will exhibit certain behavioral and developmental sequelae relative to those without the syndrome” (Dykens 1995, Dykens et al. 2000). This view holds that certain behavioral and cognitive patterns are more frequently seen in certain genetic syndromes than in persons without these syndromes, irrespective of coexistence of intellectual disability. Dykens has also noted that in few genetic syndromes certain behaviors might be unique: for example, extreme overeating in Prader–Willi or extreme self-mutilation by biting in Lesch–Nyhan syndromes as referred to in Nyhan’s original description of a behavioral phenotype. The concept of behavioral phenotypes is not espousing a genetic determinism: it does not mean that all behaviors (Table 42–9) are predetermined genetically, or that people with a certain syndrome must behave in a certain way. For example, there are individuals with Down syndrome who present with autism spectrum characteristics, more prevalent in those with severity of language and cognitive delays. Even if there is a genetic predisposition to a behavior, other factors—psychosocial, environmental, and biological
Figure 42–7  Schematic representation of transactional relationship of various factors influencing the development of adaptive and maladaptive behaviors in persons with mental retardation.

Diagnosis of Mental Disorders in Persons with Intellectual Disability

Phenomenology and Variations in Presentation

There is no evidence that mental disorders in persons whose intellectual disability are basically different from mental disorders seen in the general population. However, the clinical manifestations may be modified by many factors that include: cognitive impairment; communication skills; associated sensory, motor, and other disabilities; the environmental niche; and life experiences. The most important of these attributes is the presence or absence (or degrees of development) of verbal language. This is to be expected since many if not most of the current diagnostic criteria of mental disorders are based on a patient’s verbal productions. For instance, it might be impossible to recognize the presence of thought disorder in a nonverbal person; similar variations are also encountered in typically developing young children. The successive editions of the Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Association have tried to address this problem in different ways. Psychiatrists have been advised to assess whether the symptoms are present to a degree inconsistent with the developmental level (criteria for attention-deficit/hyperactivity disorder, DSM-IV-TR) (American Psychiatric Association 2000, p. 92). However, assessing what is the developmental level appropriate for the given individual is presumably left to the clinician’s judgment. If a person cannot describe his or her own mood, observations made by others can be substituted (criteria for major depressive episode, DSM-IV-TR) (American Psychiatric Association 2000, p. 356).

Use of Psychiatric Diagnostic Categories with Persons with Intellectual Disability

The standard criteria for the diagnosis of mental disorders can be used with almost all persons who have intellectual disability: however, they may to be modified in the context of person’s level of communication skills and developmental level (American Academy of Child and Adolescent Psychiatry 1999). With individuals who have mild degree of intellectual disability and presumably a relatively good communicative language, the usual diagnostic criteria of DSM-IV-TR can be used. These individuals, while verbal, might use simpler and concrete language. In some disorders many criteria reflect observable behaviors and vegetative signs and thus the diagnosis can be made also in persons who do not have communicative language. Obtaining detailed history from several informants who are familiar with the individual is crucial, as they can often describe changes in mood and affect, which the patient may find difficult or impossible to verbalize. The DSM-IV-TR also has “mono-symptomatic” disorders based on a domain of clinical manifestations which does not necessarily seem to be part of another mental disorder (e.g., stereotypic movement disorder) distinct from the stereotyped repetitive behaviors in autism spectrum disorders. As a last resort, a Not Otherwise Specified (NOS) category can be used. In a majority of cases, with a careful consideration and
Section VI • Disorders

assessment one can find an appropriate DSM-IV-TR category that best approximates a patient’s clinical presentation. However, it is a general consensus of the developmental disabilities clinicians that the DSM-IV-TR is not well adapted to the diagnosis of mental disorders comorbid with significant intellectual disability, especially if the person is nonverbal. There have been efforts to develop diagnostic criteria for persons with intellectual disability. A diagnostic manual for mental disorders in persons with intellectual disability, the “DM-ID,” has recently been published by the National Association on Dual Diagnosis (NADD) (Fletcher et al. 2007). This clinical guide focuses on limitations in applying DSM-IV-TR criteria to people with intellectual disability. This is a welcome addition to the many chapters on intellectual disability in psychiatric textbooks discussing how diagnostic criteria can be adapted to this population (Szymanski et al. 1998, American Academy of Child and Adolescent Psychiatry 1999). The “DC–LD” (Diagnostic Criteria for Psychiatric Disorders for Use with Adults with Learning Disabilities/Mental Retardation) (Royal College of Psychiatrists 2001), although based

primarily on professional consensus rather than on empirical data, has also been found useful in practice, especially with persons who have a moderate to profound degree of intellectual disability (Felstrom et al. 2005). In clinical field trials of 709 cases the DC–LD diagnosis and clinical assessment agreed in 96.3% (Cooper et al. 2003). Suggested modifications of diagnostic criteria are discussed below in section on specific mental disorders.

**Behavior Disorders**

A common reason for referral for psychiatric consultation is to determine whether a person with intellectual disability has a “behavior disorder” or a mental disorder. The DSM-IV-TR does not have the diagnostic category of “behavior disorder,” although it is included in the ICD-10 (World Health Organization 2006). Another commonly used term is “challenging behaviors”, which is very broad and nonspecific. It is commonly applied to aggressive and SIB. It can only indicate that the caregivers find the behavior in question challenging to them (or to their authority).

While there is no clear definition of “behavior disorder,” it is usually meant to refer to a behavioral problem that is severe enough to warrant intervention, but which is not a part of diagnosable mental disorder. It is often applied to a deliberate misbehavior, learned response, and “attention-getting” behavior. However, in the clinical presentation of every defined mental disorder, there might be elements of learned behavior—for example, caused by the responses of persons in the patient’s environment. The danger of such ill-defined, nonspecific category is that clinicians faced with a difficult case might be tempted to use it, rather than attempt to make a more specific diagnosis that might lead to a more focused treatment. Thus, it is preferable to avoid dichotomizing abnormal behaviors into “behavior” and “mental” disorders, but rather to try to decide which mental disorder the behavioral manifestations are part of (Szymanski 1994). Possibly “behavior disorder” could be employed to denote a maladaptive behavior that is clearly a function of situation and environment, and not primarily of the individual. A commonly seen example might be an individual living in a large residential institution, who in a well-staffed workshop setting is otherwise very cooperative, happy, and hardworking, but becomes irritable, negativistic, even aggressive in the afternoon, when he returns to an understaffed group where he lives. A maladaptive behavior may also serve as a form of communication if the person has poor language skills or when the caregivers do not respond to other attempts to communicate. In any case, it is essential that a comprehensive psychiatric diagnostic assessment be made to ensure that the behavior in question is not a part of a diagnosable mental disorder.

Hopefully, the future edition of the Diagnostic and Statistical Manual will be better adapted to the needs of persons with intellectual disability, especially in delineating the co-occurrence of common mental disorders. An introduction of another axis listing behavioral phenotypical manifestations, in addition to axes listing the formal diagnoses, has been recommended (Royal College of Psychiatrists 2001).

**Dual Diagnosis**

This term is used frequently when mental illness and intellectual disability coexist. However, the term remains confusing, since for most mental health professionals, it also refers to comorbidity of mental illness and substance abuse. Furthermore, often the term is used to categorize persons with comorbidity, rather than to define their heterogeneous group of disorders. Finally, the terms may lead to stigmatization of a person so labeled from an otherwise appropriate program (Szymanski and Grossman 1984).

**Assessment**

**Special Issues in the Psychiatric Assessment of Persons with Intellectual Disability**

The basic principles of the psychiatric diagnostic assessment of persons who have intellectual disability are the same as those for persons who do not have intellectual disability. However, the clinical approaches may have to be modified. The scope of the assessment might have to take into account multiple needs and problems, and in addition, these individuals depend on multiple providers for multiple services (Table 42–10). The clinical techniques have to be modified according to the patient’s discrete developmental levels in various domains, and in particular, communication skills. Not all needs and problems listed in Table 42–10 apply at all times to all individuals, but their relevance to the particular situation has to be carefully considered. In accordance with the principle of biopsychosocial integration, all these factors and their mutual interaction and contribution to the patient’s problems and general functioning must be considered. Thus, the presenting problems must be assessed in the comprehensive context of a patient’s abilities and disabilities and not as an isolated issue (Szymanski and Crocker 1989).

Such assessment may require longer time than usual, but in the long run time is saved since good diagnostic understanding of the patients and their circumstances leads to appropriate treatment rather than random trials of many therapies. A cursory ascription of comorbid mental disorders with sequential trial of medication remedies in an ad hoc manner often leads to further complications, as seen in the discussion below on psychopharmacological management of persons with intellectual disability who present with emotional and behavioral problems.

**Outline for Obtaining a History**

**Informants.** All involved caregivers should be interviewed if possible (parents, teachers, direct care workers, supervisors in
workshops). Direct care staff members (e.g., from the group home and workshop supervisors) are particularly important because they can provide a firsthand description of a person’s behavior. Exploring the following areas is important.

Reason for Referral. Most adults with intellectual disability come to the attention of a psychiatrist because they are brought by caregivers, usually because their behaviors are deemed disruptive to others. It is important to consider that not in all instances such behaviors are “maladaptive” but represent an appropriate adaptation to inappropriate environmental conditions, lack of psychosocial supports or intolerance of the caregivers. A typical example is when a person who has intellectual disability and lives in an understaffed setting discovers that the overworked staff will give attention first to those who are disruptive rather than to those who are quiet. On the other hand, a depressed individual with more internalizing problems might be neglected if quiet and not creating problems. Exploring the length of time that symptoms have been present might disclose that they have existed for a long time but that the referral has happened only now because of caregiver burnout, reduction in staffing in the facility, or other environmental changes. The caregivers’ expectation is frequently for a quick prescription of a medication remedy that has not yet been tried, to control the behavior in question. Familiarity of the prescribing physician with the program and activity schedule (and any changes thereof) of the person with intellectual disability is important.

Presenting Symptoms. Concrete, longitudinal data and a factual description of the behavior should be obtained and correlated with concurrent environmental events and treatment interventions. For example, was the aggression physical or verbal? Did it involve use of objects as weapons? Did it result in injury? Did it occur spontaneously, without obvious reason or, for example, after a staff person tried to physically force the client to comply with an order? Often, concrete behavioral data already exist, having been collected by trained behaviorists or behavioral psychologists at the school, workshop, or group home. Converting them into a graphical timeline is most helpful, as it might disclose a pattern such as correlation with other events or a cyclical nature of the presenting symptoms. It is important to find out in what situations the presenting symptoms occur as well as in what situations they do not occur. For instance, it is not uncommon to find that an individual acts aggressively at an understaffed group home but not at the workshop where structure and interesting tasks are offered, or vice versa. Obviously, psychotrophic medications may not be an answer in this case. Detailed description of any changes in mood and affect is essential, especially with nonverbal patients in new or transitional situations. Astute caregivers who know them well usually will notice depressed mood, sad appearance, anhedonia, confusion, irritability, etc.

Medication History. The history of intake of psychotrophic as well as nonpsychotrophic drugs is essential. Unfortunately, caregivers often provide only a list of drugs, dosages, and starting and discontinuation dates, without information about the reasons they were prescribed and their effects. Close to half of persons with intellectual disability referred for mental health evaluation have been found to be on nonpsychotropics that could produce psychiatric symptoms as their side effects (Royal College of Psychiatrists 2001). Common examples in this population used to be barbiturates leading to overactivity and beta-blockers leading to depression, although these practice patterns are lessening with the advent of novel psychotropic agents.

History of Complementary and Alternative Medicines (CAM). CAM treatments have been increasingly used for persons with developmental disabilities, as in the general population. Hyman and Levy (2005) in a lead article in a journal issue devoted to CAM cite studies showed that 45% of children visiting an emergency department and up to 36% of adults in the National Health Interview Survey used CAM. The parents may resort to CAM for several reasons: anecdotal reports of great effectiveness, seeking cure (about which physicians rarely talk), sense of control in managing the child’s treatment and the (erroneous) belief that these treatments are completely safe. Full review of CAM interventions is beyond the scope of this chapter and may be impossible as new ones are reported almost daily. Defining CAM is difficult and probably the best description is as a treatment, which has not been proven effective and safe in a scientific manner, which would be expected of any treatment in this era of evidence-based medicine.

Some examples include:

- Nutritional supplements (high doses of selected vitamins or multivitamin complexes, trace metals, minerals, amino acids).
- Drugs and biologicals (variably used such as piracetam, donepezil, growth hormone, secretin, cell therapy). It should be kept in mind that over-the-counter supplements are not manufactured to standards of approved drugs and it may be difficult to know the bioavailable dose of the presumably active ingredient and possibly toxic other ingredients. Some physicians have been noted to even prepare and sell proprietary mixtures of vitamins and supplements, but the parents do not know their ingredients. There have also been case reports of persons using CAM substances brought from their countries of origin which contained lead, leading to lead poisoning.
- Diets: yeasts-free, gluten and casein-free.
- Procedures: facilitated communication, auditory integration, massage, aromatherapy, facial plastic surgery for children with Down syndrome (to remove the appearance characteristic for that syndrome), and numerous others.

### Clinical Vignette 1

A four-year-old child with autism was seen for a follow-up assessment. He appeared to be grossly malnourished and had lost weight compared to an initial developmental assessment few months earlier. The child’s mother had denied any history of intercurrent illness. On close questioning about the child’s nutritional status she noted that he was recently started on yeast-free, casein-free and additive-free diet. It turned out that it eliminated most nutritional components. Intensive counseling and follow-up by a pediatrician and nutritionist was instituted and the child’s nutritional and developmental status improved.
Clinician’s attitude to the family using CAM is critical. A priori negative response, criticizing the parents or ridiculing the treatment must obviously be avoided. Optimally, the clinician should be knowledgeable with these treatments and should ask specific questions. Many families, when asked a general question about the treatments and medications the patient had been prescribed, may not mention CAM, considering them as nonmedical interventions, but will respond if the clinician asks specific questions such as enumerating all the interventions by name. If the clinician is not familiar with a given treatment, the parents might be asked to provide further information and a background literature search may indeed be done later. Firstly, all possible adverse effects of any treatment or intervention should be ruled out. Later, any available studies on the positive and adverse effects of any treatment or intervention should be ruled out. Later, indeed be done later. Firstly, all possible adverse effects of further information and a background literature search may with a given treatment, the parents might be asked to provide all the interventions by name. If the clinician is not familiar considering them as nonmedical interventions, but will respond in terms of appropriateness, consistency, and effectiveness. Often, a referral is made to the psychiatrist with the request that he or she prescribe a “chemical restraint” to “control aggression,” because the “behavioral program” did not work. A detailed history might disclose, for instance, that the aggression happens only when the person is forced to engage in a workshop in table tasks which are too difficult considering the person’s poor fine motor skills and developmentally short attention span, or that a child is overactive and irritable only at school, where he or she is placed in a classroom inappropriate to his or her developmental level. A recent vignette involved a request for the psychiatrist to prescribe elbow restraints for a young boy with Down syndrome engaging in SIB in a classroom setting without an adequate assessment of the child’s behaviors or development of a behavioral intervention program. The request was also relayed through an aide in the classroom setting without full consultation of the parents. Although such incidents occur relatively rarely and reflect urgent needs they too often also reflect an inadequate plan of care for persons with intellectual disability. The role of the psychiatrist in such circumstances is to help develop a comprehensive approach following a detailed assessment of the situation, too often not possible over a short time span. Milieu Events: Systematic exploration might be required to find out about important events such as losses (e.g., siblings moving out of the house), relocations (e.g., to a group home), or sexual abuse (as suggested by behavioral changes similar to those seen in sexually abused children). The Family: The knowledge, understanding, and reaction of family members (including siblings) to the patient’s disabilities should be explored tactfully. The psychiatrist should be careful not to convey personal feelings through the questions such as expressing condolences for their having a child with intellectual disability, whereas the parents might see the care of the child as a positive challenge. Many dedicated parents may view their child’s condition as a positive life-changing experience for them and their family. In particular, the parents should not be viewed as patients, and their normal “chronic sorrow” should not be confused with pathological depression (Olsansky 1962). The family members’ patterns of management of the patient should be explored in terms of limit setting, consistency, appropriateness of expectations to the patient’s abilities, capability to advocate for services, and participation in support activities such as parents’ organizations. Another important topic is the parents’ ability to balance the needs of the child with intellectual disability with the needs of other children.

Approaches to the Patient’s Interview
The way in which the patient’s interview is approached will depend on the patient’s communication skills and cooperation; this may range from an age-appropriate verbal
interview to observation only. The communication skills have to be explored first through brief, noncommittal conversation and questioning of the caregivers. If necessary, the caregivers might be used as interpreters of the patient’s poorly intelligible speech or sign language. Directive measures and structure are often necessary to help the patient focus, but leading questions and suppression of spontaneous expression must be avoided. While firm and clear behavioral limits may have to be established at the interview’s onset if necessary, a great deal of support is needed. Nondescending verbal and social reinforcement, as appropriate for developmental age, will let the patient know that the interviewer is appreciative of her or his abilities. The adult patients should also be approached respectfully—if possible, in a manner appropriate to the chronological age—and not as children. However, communication with them should be on the level they can understand, and their understanding should be ascertained. When asked if they understood a question, many patients tend to say “yes,” but the content of their answers may disclose the degree of understanding that needs to be attended. Persons with intellectual disability are afraid to be perceived as inadequate and instead of saying that they did not understand the question, they tend to agree with the interviewer’s last statement. Thus, asking open-ended questions is preferable to giving a choice of answers. For the same reason structured mental-status type of questions might be counter-productive. Leading questions should also be avoided. These issues need to be taken into consideration in research involving studies in persons with intellectual disability. If the level of verbal skills permits, one should always explore the patient’s self-image, including understanding of his or hers own disability as well as strengths.

Nonverbal interviewing techniques include behavioral observations, spontaneous and directed (structured) play (as developmentally and age appropriate), and other structured tasks. Optimally, the patient should be observed in normal situations such as home, school or work. While it may not be possible due to time constraints, observation of the patient in the office/clinic waiting room may provide valuable insight into general behavior, and social interaction.

**Behavioral Measurement Instruments**

There are many instruments developed for assessment of psychopathology and behavior of persons with intellectual disability (see review, O’Brien et al. 2001). They are particularly useful for nonmental health professionals as screening instruments, as well as for measuring change over time to assess treatment results. They are not meant to replace clinical diagnostic evaluation by a psychiatrist (American Academy of Child and Adolescent Psychiatry 1999). Some of them are: The Diagnostic Assessment for the Severely Handicapped (DASH-II), designed to measure emotional problems in adults with severe to profound intellectual disability, utilizing history from a primary caregiver and resulting in a clinical diagnosis based on DSM-III-R; Psychiatric Assessment Schedule for Adults with Developmental Disabilities (PAS-ADD), a semi-structured protocol for interview with the patient and a caregiver that may result in a diagnosis based on ICD-10, particularly of major depressive disorder, agoraphobia, generalized anxiety and panic disorder; Psychopathology Instrument for Mentally Retarded Adults (PIMRA), for persons with mild to moderate mental retardation, in patient and caregiver versions, that gives a diagnosis based on DSM-III (only schizophrenic and depressive symptom subscales have been validated), and Reiss Screen for Maladaptive Behavior, designed to screen for psychopathology and maladaptive behavior in adults, particularly to identify individuals needing further assessment. The ABC-Aberrant Behavior Checklist (Aman et al. 1995) has been described as more useful for adults with intellectual disability than the GAF scale (Global Assessment of Functioning) of the DSM-IV-TR (American Psychiatric Association 2000), (Shedlack et al. 2005). Finally, the Developmental Behavior Checklist (DBC), a 96-item checklist that is completed by parents or teachers is currently used to assess behavioral and emotional symptoms in children and adolescents with intellectual disability over a six-month reference period (Einfeld and Tonge 1995). Each behavioral description is scored on a 3-point likert scale where 0 = not true as far as you know, 1 = somewhat or sometimes true, and 2 = very true or often true). The DBC can be completed in 10–15 minutes and is analogous to the Child Behavior Checklist (CBCL) or Teacher Report Form (TRF) developed by Achenbach for more typically developing children and adolescents.

**Functional Analysis of Behavior**

The functional analysis of behavior usually refers to systematic collection and interpretation of data on the antecedents and consequences of the behaviors of the person in question. It is important that the focus be broad and not be restricted to immediate events but also on settings and underlying events. For instance, a person might engage in SIB when demands are made to perform in a workshop and the result might be that he or she is permitted to abandon the task. More extended analysis might show, however, that there was no such behavior in the past and that it has been occurring since the person was given new tasks that are too difficult.

**Evaluation of Clinical Data**

The clinical observations should be interpreted in light of a patient’s life experiences, learning, understanding, and communication level. The global IQ or overall mental age of a patient alone is therefore not a good guide here. In particular, the psychiatrist should:

1. Assess clinical presentation in light of the patient’s communication ability, cognitive level, associated disabilities (e.g., sensory), life experiences, environmental factors and cultural background. One should differentiate between behaviors appropriate for an earlier age and those that are pathological in any age (e.g., true hallucinations). Not all disruptive behaviors are an expression of a mental disorder: for example, an overworked staff might promote aggressive acting out by attending to the patients only when they become aggressive. However, one should not simply explain all such behaviors as attention-getting. Conversely, persons who do not manifest disruptive behaviors might have a mental disorder, for example, a depressed individual who is considered behaving well because he is very quiet. Evaluations and consultations with other disciplines should be sought as needed; these include, for example, clinical psychologists, neuropsychologists, speech and language pathologists, occupational therapists, and neurologists.
2. Assess and understand the dynamic, ongoing transactional relationships among the various factors contributing to the person’s development (see Figure 42–7).

3. Try to make a formal Axis I and/or Axis II DSM-IV-TR diagnosis (besides intellectual disability) whenever clinically justified. The diagnostic criteria can usually be adapted to the patient’s developmental level, as delineated previously. However, diagnosis does not mean listing the disorder’s code and name only. To be constructive, the diagnostic statement should include description of strengths, impairments, and need for supports and services in each discrete domain of the individual’s functioning, as well as in the environment (school/workshop, community and family). It should not merely repeat the diagnostic criteria but describe how they are satisfied in the particular case by history and clinical observation, as well as why other diagnoses in the differential are ruled out. The five dimensions of intellectual disability of the AAMR (American Association on Mental Retardation 2002) listed above are a useful guide to diagnostic assessment.

**Diagnosis of Specific Mental Disorders**

Detailed chapters in this textbook are devoted to all aspects of specific mental disorders. Therefore, in this section only aspects relevant to the diagnosis of most common mental disorders in persons who also have intellectual disability will be discussed.

**Mental Disorders Due to a General Medical Condition**

In the DSM-IV-TR, the term “Mental Disorders Due to a General Medical Condition” replaces the time-honored “Organic Mental Disorders” of earlier editions. This term is intended to be used only when “there is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition” (American Psychiatric Association 2000, p. 182). However, this category had often been used inappropriately as a catchall diagnosis on the presumption that if the person had intellectual disability which is the result of CNS dysfunction, all coexisting behavioral problems were also the product of the same neuropathological condition and a part of intellectual disability, often assumed also to be different from “normal” mental disorders. Such reasoning might be used, for instance, if a car accident at the age of 10 years caused brain injury that resulted in intellectual disability and an emergence of personality features consistent with the particular type of neuropathological condition. It would not be appropriate, for example, if a person with intellectual disability manifested symptoms consistent with psychotic disorder at the age of 15 years. The “general medical condition” should therefore be diagnosed as specifically as possible, rather than as something like “chronic encephalopathy of unknown origin” (a common diagnosis in a not-so-remote past). For mental disorder due to a general medical condition, the specific general medical condition is coded on Axis III. Of course, not diagnosing “organicity” does not necessarily mean that the symptoms are independent of CNS dysfunction.

In the DSM-IV-TR, the section Mental Disorders Due to a General Medical Condition includes Catatonic Disorders Due to a General Medical Condition, Personality Change Due to a General Medical Condition and Mental Disorders Due to a General Medical Condition Not Otherwise Specified. Other mental disorders meeting the criteria for Due to a General Medical Condition (such as mood disorders, anxiety disorders, psychotic disorders and others) are in sections on these disorders. Delirium, Dementia, and Amnestic and Other Cognitive Disorders constitute a separate section. Persons with certain intellectual disability–associated syndromes are at increased risk for developing medical conditions that produce psychiatric symptoms. For example, persons with Down syndrome are at risk for Alzheimer-type dementia. However, clinical manifestations are rarely found before age 45 to 50 years, though 75% might show them by age 60 years (Hodapp 1996).

**Diagnosis of Dementia in Persons with Intellectual Disability**

Intellectual disability can be diagnosed only if the onset is before age 18 years, whereas dementia can be technically diagnosed at any age. However, according to DSM-IV-TR, the diagnosis of dementia does not depend simply on the presence of low IQ and poor adaptive skills: both memory impairment and at least one other specified cognitive disturbance representing a decline from a previous level of functioning must be deemed present. Such decline and cognitive impairment might be difficult if not impossible to determine in infants and very young children. Therefore, DSM-IV-TR advises that making a diagnosis of dementia concurrent with intellectual disability might not be appropriate before 4–6 years of age, and in general it is not made if the condition is sufficiently characterized by the diagnosis of intellectual disability alone (American Psychiatric Association 2000, pp. 47–48). This approach avoids an automatic double diagnosis in all cases of intellectual disability from an acquired postnatal cause. However, such double diagnosis is appropriate in persons with intellectual disability who also meet criteria for dementia (such as an individual with Down syndrome, who develops Alzheimer-type dementia).

**Side Effects of Medications**

The side effects of medications are of importance in this population as the use of various drugs is frequent because of high prevalence of associated medical, neurological, and mental disorders. Common examples include: adverse behavioral symptoms associated with commonly used psychotropic medications (i.e., SSRI antidepressants and atypical antipsychotic agents), and less commonly depressive symptoms associated with beta-blockers prescribed “for aggression.” The DSM-IV-TR has a category of “Medication-Induced Adverse Effects of Medication Not Otherwise Specified” that could be used here.

**PDD and Autism Spectrum Disorders**

In the DSM-IV-TR the umbrella category of PDD is subdivided into: Autistic Disorder; Asperger’s disorder; PDD-Not otherwise Specified (PDD-NOS); Rett’s disorder; and Childhood Disintegrative Disorder. In the last two disorders (introduced in the DSM-IV-TR), deceleration in development or major skill losses are diagnostic features. PDD is increasingly referred by clinicians and researchers as a spectrum condition or autism spectrum disorder (ASD). On the one end of the
spectrum are persons with more severe impairments in social communication, language development and stereotyped behavioral disturbances with intellectual disability; on the other end of the spectrum, are individuals with normal or above average intelligence with autism or Asperger’s disorder.

PDD in general, and autistic disorder in particular, have often been confused with intellectual disability, especially when the person has a delay in speech development, is nonverbal, and manifests stereotypic and repetitive behaviors, which may also be present to a significant degree in intellectual disability. In the recent years there has been considerable concern about the rising prevalence of new diagnoses of autism (see review: Shattuck 2006). The observed increases in prevalence have, in part, been attributed to the broader DSM–IV TR (American Psychiatric Association 2000) definition of the disorder, increased public awareness, earlier diagnosis, change in diagnostic practices, better ascertainment of individuals with varying degrees of severity, and “diagnostic substitution” of autism for what in the past were attributed only to intellectual disability (Volkmar et al. 2004). Given the consistent rise in the number of new cases of autism, a true increase in the prevalence of ASD cannot be ruled out. The explanation of these trends is beyond the intended scope of this chapter. Needless to say, both the educational and health care services have witnessed a surge in the numbers of young children with ASD that may also present with varying degrees of intellectual disability, although many parents view the diagnosis of ASD as being more directive in guiding early educational services for their children. Shattuck (2006) analyzing special education data found that between 1994 and 2003 administrative prevalence of autism increased from 0.6 to 3.1/1000. About three quarters of children with core autism are believed to have some degree of intellectual disability (Fombonne 1999), although this proportion is lower in broader ASD.

In PDD, there are major impairments in interpersonal reciprocal interaction and in social communication. Conversely, persons with uncomplicated intellectual disability have an ability to relate to others (according to their developmental level). Person with very significant intellectual disability who are nonverbal may have impairments in social interactive skills. However, on closer and prolonged observation many if not most of them will demonstrate at least some nonverbal social communication skills and interpersonal attachments, to familiar caregivers who are responsive to them. Thus, intellectual disability and a PDD are not mutually exclusive, and the correct differential diagnostic question is whether the person has a PDD and whether it is associated with intellectual disability. The diagnosis can be made even in persons with significant intellectual disability and no verbal language on the basis of clinical observations and detailed developmental and current history. A diagnostic/screening instrument has also been developed to aid identification of ASD comorbid with intellectual disability (Kraijer and de Bild 2005). The diagnosis might be a problem with adults who have both autism and intellectual disability, but on whom the latter diagnosis cannot be confirmed because the early developmental history is unavailable.

In some intellectual disability–associated known syndromes clinical manifestations consistent with at least some of the presentation of autism (Clinical Vignette 2) might be found such as in fraX, and particularly TSC and 22q11.2 deletion syndrome.

---

**Clinical Vignette 2**

John, a 28-year-old man, was referred from his workplace where he was accused of sexual harassment of a female coworker. During the interview, he was anxious and fidgety, had limited eye contact, spoke in a pedantic manner, dwelling on minute details. He was well oriented and there was no evidence of psychotic thought disorder. He stated that he never had friends but wanted to have a girlfriend. He recently met a new coworker in an elevator and when she told him “see you later” he understood that she wanted to have a date. He started to bring her flowers daily and asked her out until she filed the complaint. Past history from John and his father indicated that he was always a quiet and strange child, with little eye contact, was unemotional, had no friends, was obsessive about order, and was interested only in mathematical calculations in which he was quite good. His early development was normal except that he spoke in sentences only at 4 years of age. When he was 7 years of age he was taken to a psychiatrist who thought that he had “early childhood schizophrenia” and mild intellectual disability. The parents disagreed, and he had no other contacts with mental health professionals. He attended special classes for learning disabled children and later his father arranged a job for him in the mail room of a law firm where he was a partner. Family history was negative for mental and developmental disorders. John refused to have any tests besides a psychiatric interview.

The history strongly suggested previously undiagnosed autistic disorder with some cognitive delay. Individual psychotherapy with cognitive–behavioral orientation was recommended with the focus of educating John about his condition as well as his abilities, and teaching him appropriate social behaviors and skills. He also entered a support group for young people with high functioning autism.

With his permission, several sessions were held with his coworkers who subsequently became very supportive of him.

---

**Attention-Deficit Hyperactivity and Disruptive Behavior Disorders**

Persons of any age who have intellectual disability are frequently referred to a psychiatrist with a complaint of “short attention span” (Reiss 1990, review: Antshel et al. 2006) or a disruptive behavior. Not attending, however, to school or work tasks, or not being compliant, does not necessarily warrant an automatic diagnosis of an attention-deficit/hyperactivity disorder. In the DSM-IV-TR, the majority of the diagnostic criteria for attention-deficit/hyperactivity disorder is based on observable behaviors and therefore can readily be applied to nonverbal persons, including those with intellectual disability. However, the criteria also state that the symptoms must be inconsistent with the developmental level. Thus, a high level of activity and short attention span in a 6-year-old child with severe intellectual disability, who has learned to walk recently and busily explores the environment, is not necessarily pathological. Antshel et al. (2006) after review of relevant studies concluded that attention-deficit/hyperactivity disorder may be a valid diagnosis in children with intellectual disability. They also noted that the current assessment measures of attention-deficit/hyperactivity have not been validated for persons with intellectual disability, with the exception of Aberrant Behavior...
Checklist (ABC) (Aman and Singh 1986), and that further research is needed on prevalence of attention-deficit/hyperactivity symptoms in persons with intellectual disability. In clinical practice it may not be easy to decide whether the behaviors in question are developmentally appropriate for the individual, considering developmental level, chronological age, education received, environmental factors, and presence of associated disabilities such as sensory impairments. It is important to ascertain that at least some impairment is present in two or more settings, as required by DSM-IV-TR criteria. This would help to avoid diagnosing attention-deficit/hyperactivity disorder in situations such as when the child in an inappropriate academic placement for his abilities is disruptive and inattentive at school, but not in other settings (Clinical Vignette 3). In fact, the prevalence of attention-deficit/hyperactivity in persons with intellectual disability is thought to be more threefold more common in persons without intellectual disability than in the general population (15 v. 5%).

Although less specific than attention-deficit/hyperactivity, other categories of disruptive disorder (oppositional, conduct and disruptive disorder NOS) also represent common reasons for psychiatric referral for persons with intellectual disability. This diagnosis is made in the same manner as in persons without intellectual disability, given the behaviorally specified criteria. It is essential to consider the behaviors in question in the context of the nature and severity of the intellectual disability, profile of cognitive and communication skills, appropriateness of environmental supports and services, and whether the behaviors are generalized or specific to certain settings and caregivers.

As in persons without intellectual disability, attention-deficit/hyperactivity may be associated with other disorders such as mood disorder and anxiety disorder, which should each be diagnosed even if the disruptive behavior is the reason for referral (Pearson et al. 2000).

**Clinical Vignette 3**

Billy, an 11-year-old student in a special class for children with learning disorders, was referred because he was easily frustrated, impulsive, did not finish his school assignments, refused to do his homework, did not stay in his seat, was loud in class and interrupted other children’s play. Billy had no friends and was teased by other children. His attention span was short but was better on tasks which he liked and was proficient in. He had anger outbursts and made statements such as “I am not a retard.” He had problems in falling asleep. His parents, both successful professionals, had little patience with him as did his older sister, an honor student. His full-scale IQ was 65 with marked scatter. His past neurological examination, sleep deprived EEG, and genetic assessment (including chromosomes/fragile X) were negative. During the interview he greeted the psychiatrist warmly and said that he did not want “tests” since he was not “stupid.” He talked about wanting to be a pilot or a doctor. He was markedly distractible and fidgety. When he was asked about his school he became abruptly uncooperative and angry.

Billy was seen as a child with mild intellectual disability and with symptoms suggesting attention-deficit/hyperactivity probably of the combined type, complicated by inappropriate school placement with learning disabled but bright children. He was aware of his shortcomings and rejection by peers and that his parents were disappointed with him, and his self-esteem was low. The treatment recommendations included placement in an inclusive classroom with support of a trained aide; appropriate educational supports, individual psychotherapy with the goal of improving his self-image and social skills; family therapy to facilitate his acceptance by his family; a behavioral program utilizing positive reinforcement to deal with his disruptive behavior; and a low dose stimulant medication to address his inattention and poor impulse control problems.

**Stereotypic Movement Disorder**

This diagnosis is most frequently used in persons who have intellectual disability if a stereotypic behavior is leading to significant functional impairment, if it is the focus of treatment, and if it is not better accounted for by another diagnosis. Thus, not all self-stimulatory behaviors often seen in persons with intellectual disability (and for that matter, also in persons without intellectual disability) qualify for this diagnosis. Self stimulatory-like behaviors occur in young typical children as well as in persons with blindness, especially congenital type, characteristically in the form of head turning from side to side. In fact, almost every “normal” person will engage from time to time in some stereotypic behavior such as fiddling with an object, in situations of stress or when attention is focused on a particular task such as intense studying or prayer.

The DSM-IV-TR permits adding the specification “with SIB” to the diagnosis of stereotypic movement disorder. SIB is one of the major reasons for psychiatric referral of persons with intellectual disability (rather than the stereotypy alone), especially with increasing severity and frequency and is unquestionably one of the most difficult clinical behaviors to treat effectively. SIB is defined as repetitive behavior resulting in tissue damage that requires medical treatment and that is not better accounted for by other diagnoses. Examples include head banging, self-biting, hitting, eye bashing, poking and gouging (to the point of blinding oneself), and picking at skin and body orifices. The prevalence is thought to be up to 3% of the persons with intellectual disability, but it varies—the highest prevalence being reported in persons with severe or profound disability who live in institutions and may range as high as 70%. In a study of an unselected population of persons with moderate to profound intellectual disability, 14% displayed some degree of SIB (Hillery and Mulcahy 1997). Topography of SIB may be quite varied and may include such diverse behaviors as rumination and extreme aerophagia that may be even life threatening. Risk factors (besides severity of intellectual disability) include blindness, PDD, and certain syndromes such as Cornelia de Lange syndrome, fraX, Prader–Willi syndrome (skin picking in particular), Rubinstein–Taybi syndrome and Lesch–Nyhan disorder. In the latter, some of the most dramatic and crippling self-mutilations are seen, usually inflicted by self-biting of limbs, and if restrained, of mouth and tongue. Environmental conditions are also an important factor in SIB,
either causing or maintaining the behavior that originated for different reason (see Clinical Vignette 4, below). Inappropriate, understaffed programming, overcrowding, lack of developmentally appropriate activities, and lack of staff attention unless the client displays “challenging” behavior may all contribute to development of SIB. The prevalence and severity of SIB usually peaks in adolescence and early adulthood and is reduced in later age. Unfortunately, SIB also occurs quite spontaneously and unpredictably in children with a range of developmental disorders, including autism usually associated with severe to profound intellectual disability and the sensory issues in autism may drive the SIB behaviors. A child with autism and intellectual disability with comorbid SIB is often also exhibits a range of sensory reactivity issues (e.g., clothing, food, noise) that exacerbate stereotypes repetitive behaviors; SIB being a manifestation of stereotyped repetitive behaviors that takes a life of its own once activated.

Clinical Vignette 4

David, a 20-year-old with Cornelia de Lange syndrome, with severe intellectual disability, was nonverbal and lived in a residential school. He has always engaged in some degree of self-stimulatory hand movements and head-scratching, but over the past 2 months he developed head banging that was severe enough to lead to multiple scalp cuts. A behavioral program based on time-out when he banged his head helped only when he stayed in the time-out room. A psychiatrist followed him one day at school and observed that the head banging occurred primarily just before, during, and after visits to the bathroom. On physical examination an anal fissure was found. It was successfully treated and head banging subsided for a while but then recurred to a lesser degree. David was thought to have stereotypic movement disorder not uncommon in people with Cornelia de Lange syndrome, which was later complicated by self-injurious head banging, linked initially to the painful anal fissure, but later maintained by “secondary gain,” that is avoiding tasks when he was in the time-out room. His behavioral program was modified: time-out was stopped and the head banging ceased when he started receiving rewards when he did not do it. His self-stimulatory behaviors decreased when he was started on an SSRI antidepressant.

Differentiating Stereotypic Movement Disorder from Obsessive-Compulsive Disorder (OCD) may be difficult. Compulsive behaviors in the latter are often more complex, ritualistic and involve a response to an obsession thought. However, ascertaining an obsession may not be possible with nonverbal persons with intellectual disability (American Psychiatric Association 2000, pp. 133). It is possible that a self-restraint (such as holding hands in one’s pockets to avoid self-hitting) seen sometimes in persons with intellectual disability and SIB, may be an indirect indication that this behavior is ego-dystonic, and more similar to an OCD behavior, although the ego-syntonic v. ego-dystonic distinction may be less useful in children and adolescents with OCD than perhaps in adults. Stereotypic Movement Disorder should be differentiated from motor tics, including those that occur as a side effect of a stimulant medication, and from trichotillomania that is limited to hair pulling.

In diagnostic evaluation of SIB, various underlying conditions should be ruled out. A painful and undiagnosed medical condition is not infrequently a precipitating factor: for example, an ear infection or migraine might lead to head banging. The SIB may be related to an underlying, previously undiagnosed, another mental disorder (such as depressive disorders, impulse-control disorder, and anxiety disorder) treatment of which may also ameliorate the self-injury (Tsouris et al. 2003). However, the cause of the final clinical presentation is usually multifactorial and, besides biological factors, may include learned responses to an environmental situation and coexistence of other psychopathological conditions such as depression and psychosis, treatment of which may also ameliorate the SIB. Thus, a comprehensive assessment of all possible factors is needed (Gualtieri 1989). In a fair number of patients, no underlying condition or causation can be found akin to an “essential hypertension” suggesting perhaps a multi-factorial etiology. Current studies are investigating mechanism of SIB; the possible role of endogenous opioids (Sandman 1990), dopamine receptors and serotonin systems in association with compulsive behaviors (King 1993) have been explored. A comprehensive review of the subject has been done by Harris (1995, 2006).

Pica and Eating Disorders

Pica is defined by the DSM-IV-TR as eating nonnutritive substances for at least one month, which is developmentally inappropriate and culturally not sanctioned. Pica is encountered primarily in persons with severe intellectual disability in whom it might create major health problems such as nicotine toxicity from ingesting cigarettes butts, lead toxicity due to eating lead-based paint chips or ingestion of objects that requires surgery for their removal. More than half of these individuals have been found to have zinc deficiency (Lofts et al. 1990).

Other eating disorders are also common. Up to 19% of adults with intellectual disability living in the community, and up to 42% of those in institutions may have eating disorder and obesity is frequent (review: Gravestock 2000). Persons with Down syndrome tend to be overweight, but anorexia has been also described and sometimes may occur in association with stress or loss related regression associated with depression. Overeating and obesity is a characteristic feature in Prader–Willi syndrome. Rumination is also a major health problem as it may lead to aspiration and pneumonia.

Schizophrenia and Other Psychotic Disorders

In the early years of psychiatry the differentiation between intellectual disability (especially severe) and psychosis was not clear; in particular, the self-stimulatory motor behaviors of persons with significant disability were confused with catatonia. Kraepelin’s concept of “propfschizophrenie” suggested a syndrome of schizophrenia “grafted” on intellectual disability (Catani et al. 2005). At the present true schizophrenia in persons with intellectual disability is thought to be the same disorder as in persons without; however, similar to other mental disorders in this population, the manifestations may be modified depending on developmental level and, in particular, language skills. The prevalence of schizophrenia in persons with intellectual
disability is estimated at about 2–3% (Fraser and Nolan 1994). Recent studies suggest that low intellectual ability might be a risk factor for schizophrenia and other psychotic disorders (David et al. 1997). Certain genetic syndromes also carry a heightened risk for psychotic disorders including schizophrenia. Vorstman et al. (2006) have found psychotic symptoms in 16 of 60 children with the 22q11.2 deletion (Velo-Cardio-Facial Syndrome) and in 7 of them the impairment was severe enough to warrant a formal diagnosis of psychotic disorder.

As described elsewhere in this textbook, the DSM-IV-TR diagnostic criteria for schizophrenia include delusions, hallucinations, and disorganized speech, the manifestation of which requires a certain degree of verbal language. However, the presence of grossly disorganized behavior coexisting with negative symptoms is sufficient to meet the diagnostic criteria for schizophrenia. Sometimes the person's behavior and affect might give a clue as to whether he or she is responding to visual or auditory hallucinations. In persons with some verbal language, evidence of hallucinations or delusions might be detected with careful interviewing and observation that avoid leading questions. For instance, one person with mild intellectual disability when asked if he “heard voices,” answered in the affirmative, later clarifying that he “was not deaf.” Talking to oneself, which is seen in some persons with intellectual disability as well as in ASDs, might be similar to behavior in young children who rehash the day’s events or talk to an imaginary friend, if there is no evidence that they are responding to actual auditory hallucinations. However, the nature of the hallucinations or delusions cannot be assessed unless the person has good language abilities; thus, diagnosis of a subtype of schizophrenia is not possible, and a more general category including psychotic disorder NOS may have to be used.

The lower the patient’s language abilities, the more the diagnosis has to rely on behavioral and affective manifestations. In fact, it had been suggested that an accurate diagnosis of schizophrenia may not be possible in persons with an IQ less than 50 (Reid 1993). Conversely, in persons with mild intellectual disability and good language capacities, the clinical presentation and diagnosis of schizophrenia are similar to those in persons without intellectual disability, although the content of delusional thinking might be less sophisticated. However, one should not confuse the concreteness of thinking due to reduced cognition with thought disorder of schizophrenia. Isolated, unusual beliefs have to be assessed in the context of the patient’s learning, explanations received previously, and the patient’s culture and cognitive ability to understand that these beliefs are unusual. Thus, the whole clinical picture, rather than single symptoms, has to be considered (Reiss 1992). For instance, a child with mild to moderate intellectual disability might truly believe that he hears a voice of a deceased parent admonishing him if he had been told that such an experience is possible. A good longitudinal history from caregivers who are familiar with the patient should help decide whether these features have been always present or emerged at a certain point in life and have been associated with a functional decline.

The following clinical vignettes (Clinical Vignettes 5–8) illustrate problems in diagnosis of psychotic disorders in persons with significant intellectual disability:

---

### Clinical Vignette 5

Elisabeth was referred with suspicion of paranoid psychosis. She was 25 years old. At age 5 years, she was diagnosed as having mild intellectual disability of unknown etiology. After finishing high school in special classes, she was employed cleaning tables in an office cafeteria. Four months prior to referral her parents arranged for her to live in a community residence. Around that time she was noticed to become irritable, was fearful of men, and she refused to take showers, which was ascribed to being a reaction to leaving her parents. Behavior modification program did not help. A month prior to referral she became uncooperative at work, complained that the cafeteria customers were saying that she was bad, that no one liked her, and that she was followed by people who wanted to hurt her. During the interview she was distressed, well oriented, and confirmed the above history. She denied having hallucinations. She was wearing a hearing aid. When she was asked what she meant by “bad,” she started to cry and said that she did bad things with a boy. She said that she dreamt every night about it. Her parents were interviewed and reluctantly disclosed that 5 months earlier they found that Elisabeth was sexually assailed in a shower by a 20-year-old neighbor. He was charged with rape but the defending lawyer claimed that Elisabeth agreed to have sex. She was then found to be pregnant and the parents arranged for an abortion. Elisabeth was not told what had happened to her and in fact she never had sexuality education. The parents told her that she was bad since she did not resist the man physically. Also, it transpired that the batteries of her hearing aid ran out a month prior to referral and were not changed until a day prior to her seeing the psychiatrist. Elisabeth was judged to have symptoms of Post-traumatic Stress Disorder (PTSD) related to the experiences of rape and abortion. People close to her had told her that she was a bad person. She believed it and assumed that cafeteria customers talked about it, since she could not hear them. There was no evidence of psychotic thought disorder. The recommendations included supportive psychotherapy with a female therapist experienced with persons with intellectual disability and with adjunctive course of an SSRI antidepressant. She was taught skills necessary to be a competent witness, testified in court, and the perpetrator was found guilty of raping a disabled person.

### Clinical Vignette 6

Heidi, a 23-year-old woman, was referred from her sheltered workshop because of “noncompliance.” She had Down syndrome, functioned within the severe range of intellectual disability, was nonverbal, but could understand a few verbal commands and knew some signs. Previously she had been a good worker doing simple assembly work until about 2 months earlier when she started gradually to withdraw, appeared preoccupied, and refused to do her work. The counselor, who knew her for several years, felt that her personality had changed, going from an expressive and affectionate person to becoming a “cland” one, often laughing for no reason. She still ate and slept well and liked to go on trips to shopping malls. She did not display unusual fears. There was no history of traumatic or unusual environmental events. She recently had a detailed
clinical vignette 6 continued

medical assessment which was normal, including thyroid screen and an EEG. Behavioral modification program based on “time-out” when she was noncompliant did not help. During a visit to her workshop she was observed to become intermittently preoccupied, to look around with a startled expression, and to vocalize jargon-like sounds. She backed into a corner and made gestures as though trying to push someone away. She appeared to be a little consoled when her favorite counselor approached her. Family history was positive for schizophrenia in her brother and maternal aunt. Heidi’s behavior observed during the visit suggested auditory and perhaps visual hallucinations. Due to the lack of expressive language the presence of thought disorder could not be ascertained, and only a tentative diagnosis of Psychotic Disorder NOS was made. Her symptoms did not warrant diagnosis of a mood disorder nor was there evidence of PTSD. She responded well to a low dose of an atypical neuroleptic.

Mood Disorders

Mood disorders, depression in particular, had been rarely diagnosed in the past in persons with intellectual disability, and are probably still underdiagnosed, for several reasons (Szymanski 1980b). First, it had been thought that these individuals cannot become depressed because of insufficient cognitive abilities (Gardner 1967) or, as viewed by some, that their behavior problems were learned as a result of environmental deprivation (both these views denied in effect that these persons could have normal human emotions).

Second, poor language capacities made the diagnosis difficult. Third, depressed persons who do not disturb others are often unnoticed in understaffed facilities. However, case reports on depression in persons with intellectual disability had been appearing, and the literature indicates that there is sufficient evidence that depression can occur often in this population (Sovner and Hurley 1983). The prevalence of mood disorders in persons with intellectual disability and in the general population is thought to be similar (Reiss 1994). In the field trials of DC–LD affective disorder was diagnosed in 101 of 709 cases (Cooper et al. 2003).

The majority of the DSM-IV-TR diagnostic criteria for major depressive episodes and for manic episodes can be well used even if language is poorly developed. The diagnosis in verbal persons with mild intellectual disability follows the same principles as in persons without intellectual disability. Furthermore, self-report instruments may be reliably used with them (Esbensen et al. 2005). In individuals with more significant disability who have poor communication skills the history of behavioral change observed by caregivers who know them well will help to make the diagnosis. The expression of the symptoms may be modified by the person’s developmental level and environmental factors (Szymanski et al. 1998, American Academy of Child and Adolescent Psychiatry 1999). For example: there may be no subjective report of depressed mood, but the carers could have observed change from happy to sad appearance, tearfulness, irritability. The individual may not be able to complain of anhedonia but there may be a history of refusal to engage in previously pleasurable activities. The agitation, inability to concentrate, decreased productivity at work, pacing, can be reported as well. Feelings of worthlessness may be expressed by statements such as “nobody likes me.” Teachers and counselors could have observed decrease in productivity, lack of concentration on tasks or even regression of skills. Vegetative signs can be prominent. While recurrent thoughts of death and suicidal ideation may not be verbalized, suicide does occur in women with and without mild intellectual disability at the same rate, whereas men with mild intellectual disability have suicide rate lower than men without it (Patja et al. 2001). Some individuals are referred primarily because of aggressive and other disruptive behaviors (Reiss 1994). Under pressure to perform, a person with undiagnosed depression who lacks the means to explain how she or he feels might strike out toward others in self-defense. There is an unequivocal correlation between depressed mood and poor social skills and supports (Reiss and Benson 1985). The “relocation syndrome” in persons abruptly moved to a new placement might actually lead to depression, following a loss of familiar environment and familiar social supports.

The differential diagnosis of depression may include dementia since these individuals may appear as losing skills. In persons with Down syndrome the differential diagnosis will include hypothyroidism and Alzheimer-type dementia for which these individuals are at risk. In uncomplicated depression there is usually no evidence of loss of memory. The individual might be noncompliant and may not perform even familiar tasks but this occurs because of lack of motivation. On the other hand, in dementia, a person may attempt to do a task but may have lost the necessary skills. Presence of vegetative symptoms, depressed mood, and anhedonia will support the diagnosis of depression. The diagnosis is more difficult when depression accompanies dementia. As alluded to earlier, anorexia with significant weight loss has often been clinically observed in depressed persons with Down syndrome.

The DSM-IV-TR diagnostic criteria for manic episode can be also used with persons with intellectual disability, as documented in a study of Cain and colleagues (2003). The nature of the behavior in manic episodes will be similarly affected by a person’s adaptive skills and opportunities. A persistently elevated, irritable mood may be expressed in noisy and agitated behavior, aggression and noncompliance. Unrealistic behavior unusual for the individual (e.g., attempts to drive a car) sometimes may reflect grandiosity or elated expectations. Unlike in typical subjects with hypomanic/manic behaviors, persons with intellectual disability and elated mood with no money or credit cards will not go on shopping sprees, but may engage in confused, disruptive, overactive behavior, screaming, aggression and destructiveness. Sudden inappropriate sexual behavior may be seen as well (American Academy of Child and Adolescent Psychiatry 1999). Rapid cycling bipolar disorder has been also described in this population, with mood, behavioral and vegetative changes occurring as frequently as every several days.

The issue of cyclical behavior changes has to be approached carefully as it may not necessarily be an evidence of the cyclic affective disorder, but may reflect behavior changes in response to environmental events such as staff changes in residential facilities. It may even be a sign of mood disorder with seasonal features (seasonal affective
Clinical Vignette 7

Daniel, a 28-year-old man with Down syndrome and mild-to-moderate intellectual disability, was the older child of two surgeons and had a 3-year younger brother, a brilliant college graduate. Daniel had a history of excellent adjustment, pleasant personality, had been friendly and active in community activities, and held a job at the local Pizza Hut. Two years prior to referral his brother married and moved out of the house. Daniel was the best man at his brother’s wedding. Soon after that he appeared preoccupied and started asking why he could not marry. His parents were at loss as what to answer. He became sad, had trouble sleeping, lost weight, did not enjoy his work or recreation, and gradually stopped talking almost entirely. Neurological and medical assessments, including thyroid screen, were negative. His counselor at his day program felt that Daniel was just trying to get attention and initiated a behavior modification program that included punishment (spraying ammonia into his face) if he was noncompliant, with no improvement. He was put by his family physician on a SSRI antidepressant which helped only initially and was stopped because of agitation. His father’s psychiatric colleague (with no experience in intellectual disability) suggested a course of ECT, as according to him, no other treatment worked with people with Down syndrome. Daniel received a total of 70 ECTs in the course of a year, which resulted in moderate memory loss but otherwise no improvement. During the interview Daniel had a sad expression with evidence of psychomotor retardation. He did not talk but appeared listening and became fidgety when the psychiatrist suggested that he probably missed his brother and felt lonely.

By history, Daniel had developed major depressive disorder following his brother’s wedding and he was probably eager to talk about it, but apparently no one responded. The punitive behavioral treatment and later ECT, if anything, deepened his depression. A recommendation of supportive psychotherapy, another trial of an antidepressant, and a behavioral program based on positive reinforcement was made.

Clinical Vignette 8

Barbara was diagnosed at 3 years of age with severe intellectual disability due to marked delay in her global development. Exhaustive genetic evaluation failed to clarify its etiology. She never developed expressive speech, but understood simple commands and knew about 30 signs. She lived with her very supportive parents, attended special classes and was a friendly, well-related and pleasant person. At 17 years of age she became gradually withdrawn, cried often, did not enjoy car rides with her parents (previously her favorite activity), lost appetite and weight, and slept poorly. When she was pressed to complete school tasks she became aggressive, prompting psychiatric referral. She was diagnosed with a major depressive episode and was put on an SSRI antidepressant. Over the next 2 months she gradually improved. Her appetite returned, she became cooperative, and slept better. However, in the third month she again developed insomnia, roamed the house at night singing or screaming, was hyperactive, laughed for no obvious reason, and became aggressive if told to go to sleep. Detailed medical evaluation failed to disclose any general medical condition. There was no history of traumatic environmental events. She was diagnosed as having a psychotic episode and treated with an atypical neuroleptic. She improved dramatically at first, but in a month she was where she started; presenting with the same symptoms that led initially to the diagnosis of depression. This time a diagnosis of Bipolar Disorder NOS was made and she was treated with carbamazepine. She improved rapidly. Her mood stabilized, she slept and ate well, again became cooperative at school and home and returned to her “old self.”

Anxiety Disorders

Various types of anxiety disorders have been described in this population (review Bailey and Andrews 2003). It is important to distinguish between anxiety as a transient symptom and as a manifestation of an anxiety disorder in which the required diagnostic criteria are fully endorsed and the severity is such that distress or functional impairment are present. Situational anxiety is common in persons with intellectual disability who are exposed to stresses that they find difficult to cope with; in some ways the anxiety serves a protective role helping to avoid uncertain situations. Conversely, lack of anxiety in persons who do not understand that a certain situation is unsafe, may expose them to danger; for example, running across the street disregarding the traffic. As with other mental disorders, anxiety disorders in persons with mild intellectual disability and good language skills are manifested and diagnosed in essentially the same manner as in the general population. In individuals with lower functioning and lesser language skills, behavioral expression of anxiety may predominate (review: Bailey and Andrews 2003). This may include irritability, crying, hiding, agitation, SIB and aggression. In these individuals the diagnosis is more difficult, but many DSM-IV-TR criteria are based on observable behaviors that can be ascertained in them. Generalized anxiety disorder may be manifested by restlessness, reduced concentration, irritability, muscular tension, and diaphoresis, as well as sleep disturbance. The worries, if not verbalized, will have to be inferred from the individual’s general behaviors. The underlying concerns might go undiagnosed if the person resorts to disruptive behaviors on which the caregivers focus instead. While panic disorders have been reported in this population, there is a possibility that an episode of otherwise unexplained aggression may in fact be a panic attack; phobias have been described in this population as well (review: Bailey and Andrews 2003). These include agoraphobia, social phobia and various specific phobias. The predominant symptoms might be behavioral, as the individual might not be able to recognize (and describe) the fears as excessive or unreasonable. If he or she tries to avoid the phobic situation, the caregivers may not understand it, may think that he just has a behavior problem, and may force him to be exposed to the phobic stimuli. The individual might then resort to aggressive behavior, which might then become the focus of treatment. As in diagnosis of all mental disorders in this population, the symptoms...
have to be interpreted in light of individual’s developmental level/cognitive skills. For example, he/she may not be able to recognize that the fear is excessive or unreasonable. DSM IV-TR acknowledges that in children this feature may be absent: the same may apply to adults with significant intellectual disability. In fears related to certain places or individuals, the possibility of posttraumatic stress disorder (e.g., caused by abuse that the person cannot describe) has to be considered, as well as realistic fear of harm. For example, an individual who fears to stay in his room in a residence, may be afraid of a new, aggressive roommate, rather than have claustrophobia. Avoidance of others by persons with intellectual disability and undiagnosed autistic disorder might be misdiagnosed as social phobia. Increased prevalence of anxiety disorders has been described in Williams syndrome, Fragile-X syndrome, as well as Down syndrome.

Posttraumatic Stress Disorder (PTSD)
This disorder occurs in this population but is probably underdiagnosed, since persons with reduced communication skills may not be able to report what had happened to him or her. Ryan (1994) reported on a series of 51 individuals with intellectual disability who met the DSM-III-R criteria for PTSD. Turk et al. (2005) who reviewed the relevant literature and report on two persons with Fragile-X syndrome and PTSD stress the need to view the presenting symptoms in light of premorbid functioning as a baseline. The DSM-IV-TR diagnostic criteria include history of an exposure to an event “that involved actual or threatened death or a serious injury” (American Psychiatric Association 2000, p. 467). However, a person with significant intellectual disability may not recognize it or, conversely, may perceive as threatening events that are not traumatic to an average age-peer. Thus, the individual’s understanding of the event in question has to be carefully explored. The criteria also include modifications applicable to children which can be applicable to persons with developmental level below their chronological age. It should be kept in mind that a person with intellectual disability who was nonviolently sexually abused may not (at least immediately) realize that it was an abuse and may not react with fear, helplessness, or horror as apparently required by the criteria. In fact, sometimes, sexual abuse/exploitation is perceived as an expression of “friendship” by persons who are routinely rejected by their “normal” peers. Thus PTSD should be always considered as a differential diagnosis in this population.

Obsessive Compulsive Disorder (OCD)
In persons with mild intellectual disability and good verbal skills the diagnosis may be made using the standard diagnostic criteria. The differential diagnosis from ritualistic behaviors, and perseverations, and stereotypies such as those seen in stereotypic movement disorder may be difficult if the person does not have sufficient language to describe the persistent and intrusive thoughts that cause the anxiety, which the compulsions are designed to prevent, nor that it is ego-dystonic. The latter can sometimes be inferred from observable behavior such as self-restraint to prevent self-injury. The DSM-IV-TR provides a qualifier “with poor insight” if the persons cannot recognize that the obsessions and compulsions are unreasonable and excessive. Compulsive behaviors in persons with intellectual disability might be misdiagnosed as stereotypic movement disorder. Conversely, stereotypic behaviors in persons with significant intellectual disability (especially comorbid with pervasive developmental disorder) might be misdiagnosed as OCD. Adherence to routines might also be adaptive and even encouraged by the caregivers.

The possibility of relationship of OCD and SIB/stereotypic movement disorder has been raised. Both include repetitive behaviors. However, SIB, in contrast to OCD, tends to be more frequent in people with lower IQ.

Personality Disorders
Over the years, many myths have accumulated concerning the personality patterns of persons with intellectual disability—that they have uniform personality features resulting from organic brain damage and that they all are aggressive, passive, and dependent. Actually, these persons display a spectrum of personality traits that is as wide as that in the general population. Three factors that are generally common to persons with intellectual disability and that might influence their behavioral traits have been suggested: cognitive deficits (underlying, for instance, concrete thinking), neurological dysfunction (sometimes leading to a short attention span), and adverse environmental experiences that lead to changes in behavior (Szynanski and Crocker 1989). The DSM-IV-TR differentiates between personality traits and personality disorders. The former are “enduring patterns of perceiving, relating to, and thinking about the environment and oneself (American Psychiatric Association 2000).” Thus, they are part of a person’s uniqueness and are not necessarily maladaptive. In contrast, personality disorders are diagnosed when the traits are maladaptive, inflexible, and lead to significant distress or impairment in functioning. Usually they are diagnosed in adolescence or early adulthood, but if they are diagnosed before age 18 years, the symptoms must have been present for at least 1 year. They are assessed in the context of a person’s culture, age, social background, habits, customs, and values. This is particularly relevant in the case of persons who have intellectual disability and those in whom learning and living opportunities are unusual—for example, living in institutions or being sheltered by their families. The caregivers not infrequently reward passivity, dependence, and overcompliance. The depriving institutional environments teach the individual that attention-seeking and disruptive behaviors bring attention from the staff, even if the attention is negative. The reactions of the important persons and realization of the differences between oneself and one’s peers often lead to a low self-image. The last is probably the closest to a universal personality feature of persons with intellectual disability.

Various studies have described maladaptive personality features in up to 56% of persons with intellectual disability, which have been seen as underlying the high prevalence of psychopathological conditions in this population (Reiss 1994). All types of personality disorders might be seen. The diagnosis of dependent personality disorder might be difficult because dependency on others might be based on reality resulting from a lack of various skills. Avoidance traits may be seen in persons with fraX who avert their gaze and are prone to anxiety. Borderline personality disorder might be seen in persons with a mild degree of ID.
Aggression

Aggressive behavior directed against people or property (destructiveness) is one of the most frequent reasons (if not the most frequent) for referring persons with intellectual disability to a psychiatrist and an important factor preventing successful inclusion in the community. The actual behaviors may range from occasional swearing (verbal aggression) to serious violence (Harris 1995). In a recent Canadian survey of service providers for adults with intellectual disability living in the community, over half were reported as exhibiting aggression in the past year; about one-quarter being physical aggression (Crocker et al. 2006). As expected, persons with more severe disability (and poor communication skills) tended to physical aggression while those with milder disability towards verbal aggression. Whether a particular behavior is called aggression (except for clear physical aggression) depends on the caregiver's perception. Thus, in obtaining the history it is necessary to obtain a concrete description of the behavior in question, preferably from several informants. Prolonged direct observation of the patient may be necessary to resolve unclear cases. Aggression is a behavioral symptom and not a single diagnostic entity or disorder, nor does it have a singular underlying explanation. Thus one cannot talk about a unique treatment for aggression (except for symptomatic emergency measures). Psychiatrists are often asked how they treat aggression in persons with intellectual disability. The answer is, of course, that it is done in the same manner as in persons without intellectual disability: an accurate diagnostic assessment comes first. Different factors must be considered in assessing the cause of aggressive behavior (Harris 1995, 2006). It might be associated with a defined mental disorder, for example, psychosis (e.g., aggression following a command hallucination, a delusion), anxiety, borderline or antisocial personality, or depression. It may occur as a part of akathisia after rapid withdrawal of a medication. The factor of learning will reinforce aggressive behavior if it brings a reinforcing response by the caregivers. A pathological brain condition such as rage attacks after brain injury or associated with complex-partial seizures, may also lead to aggression. Often, several causative factors are involved, all of which require evaluation and intervention.

The DSM-IV-TR has a category of Intermittent Explosive Disorder that can be used, provided that another mental disorder has been ruled out as the cause of the aggressive behavior.

Adjustment Disorders

Emotional or behavioral symptoms that are a response to a stressor, that cause distress or functional impairment, and that are not related to another Axis I disorder, are categorized as adjustment disorders. One example of such a stressor, common in the lives of persons with intellectual disability, is a precipitous move to an unfamiliar living or school setting, as the result of which the individual becomes confused and anxious, and exhibits maladaptive behavior. Another example might be when an adolescent with mild intellectual disability is teased, called a “retard,” and told that he or she will never have a girlfriend or boyfriend or live independently. In such situations, a variety of behaviors emerge ranging from depressed mood to imitating the acting out of his adolescent nondisabled peers. The condition might become chronic because the stressor never really disappears.

Forensic and Legal Issues in Intellectual Disability

Criminal Behavior

Following introduction of IQ testing in the early 20th century, it was soon discovered that many criminal offenders tested within the intellectual disability range (including “borderline mental retardation” range). This led to the concept of “moral morons” or “moral imbecility,” and the belief that intellectual disability predisposed to crime. Pseudo-scientific studies such as “The Kallikaks” by Goddard in 1912 (published by the Breeder’s Association), purported to show the inheritance of intellectual disability and antisocial behavior through several generations. No consideration was given to factors such as poverty and lack of education.

There are no accurate epidemiological data on prevalence of criminality among persons with intellectual disability, for several, chiefly methodological, reasons. Not all jurisdictions routinely do diagnostic cognitive assessment of offenders and those that do, usually limit it to IQ tests (often group ones) and use various instruments. There is an agreement that persons with intellectual disability are over-represented in the prison population, at rates from 4% to a high (in Western Australia) of 20% (reviews: Riches et al. 2006, Petersilia 1997). There may be several factors involved here. Persons with intellectual disability are more likely to be arrested as they may lack cunning to avoid it. They may be exploited by nondisabled criminals who encourage them to commit an offense. They may admit to an offense which they did not commit, in order to please the police or even to present themselves as savvy criminals. Police and court personnel may not recognize their disability, or conversely, may release them even if clearly guilty. Prisoners with intellectual disability are at serious risk of abuse or exploitation by other inmates and have less chance for parole as they may not have enough skills to conform to prison rules. Some states have special diversion programs in the community to rehabilitate offenders with intellectual disability.

Competency to stand trial question is usually brought up if the disability is obvious. In most jurisdictions the law does not differentiate between intellectual disability and mental illness. The diagnosis of either is not a priori an evidence of incompetency. Competency to stand trial includes ability to understand the charges, the consequences if convicted, and an ability to aid the attorney in the defense. Depending on their jurisdiction, person deemed not competent to stand trial, may be committed (and recommitted) to a mental hospital for evaluation. Following a landmark U.S. Supreme Court decision in Jackson v. Indiana in 1972, there is a maximum time an incompetent person can be held without having a trial, or being committed under civil statutes.

Insanity defense is used rarely for persons with intellectual disability, although technically it can. A person with significant disability may commit an offense without knowing that it is an offense but usually he/she is not charged criminally, but released to caregivers, or hospitalized.

Competency to testify (or rather its lack) is often brought up in defense of an offender against a person with disability. For example a person accused of a rape of an
intelligently disabled woman routinely claims that she is not competent to testify against him. (Conversely, the claim may be that she was competent to give a valid consent for consensual sex). The diagnosis of intellectual disability does not automatically disqualify the witness. To be competent, the witness has to understand the concept of truth and perjury, and has to be able to recollect and to describe relevant events. A person with intellectual disability may feel intimidated in the courtroom and therefore in some jurisdictions may be permitted to testify separately via video, similarly to a child witness.

**Death penalty** for persons with intellectual disability has been a hot topic in the recent years. State laws varied in this respect. In a landmark case of Atkins v. Virginia in 2002, the U.S. Supreme Court ruled that “execution of criminals who were mentally retarded is held to constitute cruel and unusual punishment in violation of Federal Constitution’s Eighth Amendment.”

**Roles of psychiatrists.** Psychiatrists are usually called to perform competency assessment. They should be well versed in the legal definition of competency in question in their jurisdiction. The usual principles of obtaining history and interviewing should be followed, as described earlier in this chapter. Considerable time may be required to gain the individual’s cooperation. The focus should be not primarily on the diagnosis of intellectual disability but on assessing discreet skills required for the particular competency. For example, to be a competent witness the person should understand the concept of truth; the need to tell the truth; the penalty for perjury; have ability to recall and describe events; and differentiate between own fantasy and observed facts. The past history in this respect is important as well.

**Noncriminal forensic issues**

**Guardianship.** Up to the age of majority (18 in most jurisdictions) a person is not considered fully legally competent and the parents (or legal guardians) are responsible for him/her. Upon achieving that age every person is presumed to be a legally competent adult, unless a court rules that he/she is not competent and appoints a legal guardian. The diagnosis of intellectual disability does not automatically mean incompetence. Most states now recognize partial competency, in that a person may make certain decisions and a guardian makes other decisions, typically concerning major medical treatments, program changes or money matters. The guardian’s powers are also limited. Typically the guardian cannot consent to sterilization or to institutionalization: court order is necessary for that. Any clinician caring for an individual approaching age of majority should advise the family to apply to the court for competency determination. This determination in most jurisdictions involves examination by a licensed social worker and psychiatrist or other physician, who are trained and/or experienced in the field of intellectual disability.

**Parental competency in child protection cases.** Psychiatric assessment is often requested in these cases. Parents who have intellectual disability are overrepresented here, primarily on charges of neglect rather than abuse. The presence of the disability does not disqualify a parent: rather lack of parental competency has to be proven, as with any other parent in such case (except when a woman with severe/profound disability, usually with a history of being raped, delivers a child). Many advocates for rights of persons with intellectual disability argue for their right to be parents, and for their right to receive all services and supports to enable them to be successful in this respect. There is little reliable literature on persons with intellectual disability as parents. Marč et al. (1997) surveyed all public health nurses in Norway (where health care, prenatal care and social support services are some of the best and universal) concerning children born to parents with intellectual disability. They identified 126 children who had at least one parent with intellectual disability and estimated the prevalence to be 430 children under 16 (in a population of 4 million). In this study sample 43% of the children appeared to have learning difficulties and 40% “suffered of failures of care.” The problems that often compound parent’s difficulties include poor parenting and independence skills, financial and housing problems, lack of support (many are single mothers), inability to find and access services. Many of these parents can function relatively well with supports as long as they have one young child, but fail when they have to deal with additional children, with different needs and personalities, and especially when the child achieves adolescence and strives for own independence.

**Overall Goals of Psychiatric Treatment of Persons with Intellectual Disability**

The overall goal of all medical therapies, including psychiatric care of persons with intellectual disability, is to promote the optimal growth and development and ensure optimal physical, emotional, and social well-being of individuals concerned. Treatment of persons with intellectual disability therefore involves multimodal approaches. In addition to psychiatric interventions that will be described in this section, parental support and counseling, special education, speech and language, occupational, and physical therapies, sensory integration therapy, and social skill training may also help to assure optimal outcome. The goals of psychiatric treatment are to minimize symptoms associated with a specific mental disorder, prevent harmful behaviors (e.g., aggression, SIB), facilitate access to educational, social and community inclusion programs, maximize beneficial effects of nonmedical interventions, and improve the quality of life for the individual and the family.

Treatment is aimed at helping to facilitate improved functionality in educational, social and community settings. Psychiatrists should understand the indications for, side effects of, and limitations of any therapeutic intervention. The individual with intellectual disability and their families should be involved in the treatment planning process as much as possible, despite any developmental limitations. Every effort should be made to help the individual understand the reasons for the treatment, expected results, and possible side effects. This approach will prevent the development of negative attitudes or misperceptions toward the use of the psychotropic medication in these individuals. When this is done, the individual becomes an effective partner in the intervention (Tsai 2001).

The most common mistake made by mental health clinicians treating persons with intellectual disability is to consider suppression (usually with medications) of single problems (as a rule disruptive behavior) as the only goal of
treatment. This approach has been the rule in the past when people with intellectual disability were not expected to achieve any measure of independence; keeping them docile was deemed to be a more important goal. Such approaches are reemerging, partly related to pressures to achieve a fast and inexpensive symptomatic improvement. Fortunately, in the past three decades the concept of the quality of life (QOL) has been assuming a central role as the goal of treatment of persons with intellectual disability. Numerous scales to measure the QOL have been designed, usually focused on concrete indicators related to factors such as services or health and typically reflecting the view of the caregivers. More recently the importance of the subjective aspects of QOL has been stressed: the individual’s subjective feeling of contentment, well-being, and satisfaction with own life as opposed to the caregiver’s satisfaction. In other words, personal happiness of the person with mental retardation is now stressed as a goal of habilitation as well as the person’s need for various supports (see Figure 42–6). Based on the observation.

1. Comprehensive diagnostic understanding. Based on the psychosocial model of the interaction of the various factors (see Figure 42–6), this should follow the guidelines described earlier. The purpose is not to elucidate and treat a single diagnosis (e.g., treating depression with an antidepressant) but to understand all factors causing and perpetuating the problem, and the patient’s strengths, which should be developed. The diagnostic evaluation should consider past and developmental history and include detailed patient interview or observation.

2. Developing goals of treatment. Both the ultimate goal and the intermediate objectives should be established. For instance, the goal might be elimination of depression and preparation for a more to semi-independent living. The intermediate objectives might include amelioration of insomnia, anhedonia, and aggressive outbursts.

3. Developing treatment priorities. If possible, less intrusive and simpler approaches might be tried first, for example, manipulation of the milieu. If these efforts are unsuccessful, other approaches might be tried, for example, medications. Often the treatments have a synergistic effect and should be used together. For instance, stimulants might improve a person’s attention and reduce impulsivity, making the patient more responsive to behavioral therapy that teaches methods of appropriately expressing refusal, rather than through aggression.

4. Monitoring treatment results. Because multiple caregivers may be involved, it may be difficult to obtain consistent, reliable, and concrete data. Using a behavioral rating scale, or even developing a simple one for a particular patient, helps measure the behaviors or symptoms and monitor progress. Such objective data are essential as global caregivers’ impressions, although important, may be misleading. For instance, caregivers might feel safer knowing that a patient is on medication and might report behavior as improved, while data might not support that.

5. Avoidance of indefinite treatment. The treatment should be result driven, that is, it should be continued only and as long as it can be proven, by measurable results, to be effective.

6. Team collaboration. All involved caregivers, including family and professionals, should be in agreement about the nature, goals, side effects, and results of the treatment. This can be achieved by open discussion and education and is especially important when psychotropic drugs are used. If some difference of opinion remains concerning which treatment should be used, the team can agree on the order in which the various approaches should be tried (usually the least intrusive ones are used first).

Pharmacotherapy

Legacy of Inappropriate Use of Psychotropic Drugs

Psychotropic agents and traditional antipsychotic medications in particular have had a long legacy of indiscriminate use in persons with intellectual disability, especially among those residing in large residential institutions. These agents were used nonspecifically, primarily highlighting their (side) effects to induce docility and suppress disruptive behaviors, even though such behaviors may have been appropriate reactions to abnormal, understaffed, institutional, depriving environments (Tu and Smith 1983). The early epidemiological research on the use of psychotropic agents focused on their pattern of use in residential facilities. In the 1970s, up to 86% of residents were receiving these drugs, and more than half of these drugs were antipsychotic agents (Rinck 1998).
The abuse of psychotropic agents inevitably led to a backlash, mostly among nonmedical professionals, resulting in hostility to the use of any medications, even if they were clearly indicated for the treatment of a diagnosed mental disorder. The early standards of institutional care were set by Health Care Financing Administration (HCFA), currently known as Centers for Medicare and Medicaid Services (CMMS). It perpetuated the image of psychotropic agents as harmful and to be used only as a last resort. Such attitudes, which are still encountered, in effect deny persons with intellectual disability appropriate medication treatment for mental disorders. Some institutional administrators engaged in a sort of “numbers game,” seeing the lower percentage of individuals in a program who are receiving psychotropic agents as an indicator that their program was better. The percentages however were deceptive; with well-adjusted persons being transferred to the community, institutions became de facto mental hospitals predominantly for persons with mental disorders and intellectual disability. Thus, it was no surprise that many residents were maintained on these agents. More important however is that a large proportion of individuals receiving psychotropics did not need these agents, and many persons with intellectual disability did not receive any drugs that would otherwise have benefited from them.

The widespread inappropriate use of psychotropic drugs among persons with intellectual disability also made them an early target of class action suits on behalf of residents of large, public institutions. The 1971 Supreme Court Wyatt v. Stickney decision which ruled unconstitutional the way mental health patients were warehoused in state institutions for long periods of time without treatment also stated that, “residents shall have a right to be free from unnecessary or excessive medication . . . Medication shall not be used as punishment, for the convenience of staff, as a substitute for a habilitative program, or in quantities that interfere with the resident’s habilitation program” (Rinck 1998).

It is of interest that early research on individuals residing in the community indicated low rates of psychotropic use, in the 20–30% range, depending on the study (Rinck 1998). It appears that these rates might now be higher, possibly reflecting pressures for quick symptomatic treatment. It is not unusual to encounter individuals who were successfully weaned off medications in institutions but were quickly back on them when placed in the community, at the first sign of behavioral problems, even if they were a normal and transient reaction to the stress of relocation.

Research on the effectiveness of psychotropic drugs in persons with intellectual disability has also been affected by methodological shortcomings, including small sample size, lack of control groups, treatment of nonspecific symptoms, and inherent tendency not to report negative findings (Bregman 1991). The reliability of diagnoses was also unclear, especially since diagnoses could sometimes be made post hoc, to justify the use of medication. There is also no uniform agreement on the definition of psychotropic drug use. For instance, certain drugs may have both medical and psychiatric uses such as anticonvulsants, that are used both for the treatment of seizures and for affective disorders. There is no convincing evidence that there is a different response to psychotropic drugs in persons with and those without intellectual disability, all other factors being equal (Bregman 1991).

Yet, most of the existing studies have been on the effectiveness of a drug on a nonspecific group of persons with intellectual disability, without consideration of the etiology of the intellectual disability. More appropriate would be studies of drug action in persons with intellectual disability of a specific etiology compared with their action on persons with the same mental disorder but without intellectual disability. What still remains different in the pharmacotherapy of persons with intellectual disability is the difficulty of making an accurate diagnosis of comorbid mental disorders and the special need for concurrent interventions in this population.

**General Considerations**

The modern approach to rational use of psychotropics among persons with individual disability is reflected in the new 1997 HCFA (CMMS) guidelines. The main points of the HCFA guidelines include:

1. Prior to use of any psychotropic medications: rule-out medical, psychosocial, and other causes for presenting problems; document diagnosis and differential diagnosis; first try less intrusive interventions, including psychotherapy, as appropriate; and collect baseline behavioral data.
2. After psychotropic medication has been started: it must be a part of comprehensive treatment program; it should not interfere with the patient’s functioning; adverse reactions should be monitored; drug effectiveness should be monitored, including effect on quality of life; dose reduction should be considered if not clinically contraindicated (American Academy of Child and Adolescent Psychiatry 1999).

In principle, the use of psychotropic drugs for persons with intellectual disability does not inherently differ from their use with persons without intellectual disability. Therefore, as psychopharmacology is dealt with extensively elsewhere in this book, only some issues relevant to persons with intellectual disability are mentioned in this section. Some misperceptions remain. Although persons without any intellectual disability are usually treated with drugs for major depressive disorder, schizophrenia, and so on, unfortunately, it is still a common practice to prescribe psychotropic agents for persons with intellectual disability for nonspecific “behavioral difficulties.” In one study, only 25% of persons receiving psychotropic agents had a formal psychiatric diagnosis (it is not clear how many had an adequate, comprehensive assessment rather than just a label) (Jacobson 1988). It is therefore important to emphasize at the outset that such nonspecific treatment does not make sense. For example, aggressive behavior might be part of the presentation of major depressive disorder, anxiety, psychosis, or even a justified anger in an otherwise mentally healthy person. Each of these situations requires different treatment strategies; it is illogical to refer to a single treatment “for aggression” but nevertheless this practice survives disproportionately more in the practice of pharmacotherapy among persons with intellectual disability. The practice is often encountered in institutional settings, especially those lacking in habilitative programs.

Another practice is a “Christmas Tree Approach”: this approach reflects adding subsequent drugs, without
discontinuing the previous ones which failed to reduce the undesirable behaviors, in the absence of any evidence that the combination has a synergistic effect. Some individuals, especially those in institutions, have therefore ended up taking a combination of psychotropic agents without evidence that any one of them has been effective. A more effective approach is to introduce a systematic follow-up with regular assessments as noted earlier. However, the practice of pharmacotherapy should neither focus on nonspecific set of behaviors, nor should it focus on a single target behavior, but on a person’s global functioning. Some follow-up approaches follow the premise (without basis) that there is a linear relationship between the drug dose and the frequency of certain behavior and attempt to titrate the drug accordingly. Periodic tapering of the drug (unless clinically contraindicated) should also be considered in a rational manner when necessary to ascertain its effectiveness.

**Principles of Pharmacological Interventions in Persons with Intellectual Disability**

Where necessary and possible, a functional behavioral analysis should be carried out before the initiation of pharmacological intervention. Other factors to be considered, aside from the appropriateness of an individual’s educational or vocational program, include deciding whether the targeted symptoms might more likely respond to educational or behavioral interventions (Melmed et al. 2006). When considering pharmacological intervention within the context of an associated mental disorder, target outcomes are identified and assigned a rating of frequency, duration or severity. These target behaviors may change with a person’s chronological age or as the person progresses developmentally. If target outcomes are not met, a reevaluation of the treatment plan is in order to reconsider the scope of treatments and any challenges with compliance or adherence to the plan by all those involved in the individual care. The presence of other disorders that might be compounding or aggravating the underlying problems ought also to be considered. Specifying appropriate target outcomes, especially when long-term treatment is envisioned, can help parents who are often overwhelmed and need encouragement. Symptom severity monitoring should in and of itself help to provide positive reinforcement to caregivers, especially when improvements in functioning, however small, can be ascertained.

Pharmacological intervention in persons with intellectual disability ought to be carefully considered in association with a clear sense of what is being treated and what the expected outcomes are (Melmed et al. 2006). Intervention can be grouped under the following main objectives:

1. Improvement of interfering *primary symptoms* associated with co-occurring mental disorder in persons with intellectual disability; there is no medication (psychotropic or otherwise) that is specifically effective in treating intellectual disability per se.
2. Improvement of *secondary symptoms* associated with a co-occurring mental disorder (e.g., as in inattention, disruptive behaviors, tantrums, self-injurious, or aggressive behaviors seen in autism and intellectual disability). These symptoms can also occur as a maladaptive response to transitions, sensory stimulation, poor communication ability, and regulatory skills; thus, it is important to address these concerns with a combined behavioral modification and pharmacological approach.

There is a paucity of well-designed randomized clinical trials involving mental disorder in persons with intellectual disability. Therefore, as a first general principle, it is important to start with the lowest recommended dose and titrate the dose upward slowly, as persons with intellectual disability may be particularly sensitive to side effects such as disinhibition, irritability, and reduced sleep. Their interpretation and ability to report the physical sensation of the side effects might also vary significantly. As a second general principle in prescribing medication in individuals with intellectual disability it is important to simplify the medication schedule in terms of the number of concurrently administered medications; use of low dose of medication and titrating doses up/down with care for any emerging side effects, especially with respect to behavioral activation, oversedation, and cognitive interference. Vital signs and growth parameters ought to be measured as recommended for each class of psychotropic medication as described elsewhere in this textbook for typical populations.

Periodic discontinuation of medication is also recommended. Treatment may not be needed when behavioral and environmental variables are in flux. Psychiatrists working with persons with intellectual disability should familiarize themselves with the need for combined psychosocial and educational strategies and should not prescribe psychotropic medications with inadequate information, aiming, for example, for symptom suppression seemingly without consideration of the potential negative impact of the medication on the demeanor, adaptive functioning, or quality of life of the individual.

A school age child with an intellectual disability who is acting up secondary to a great deal of sensory stimulation in an inappropriate educational setting is unlikely to respond to short-term pharmacological strategies, especially if this strategy is urgently requested as a means of behavioral control. Pharmacological interventions, therefore, should be especially integrated as part of a child’s IEP. Obstacles to the success of such an integrated approach to pharmacotherapy are summarized in Table 42–11 below.

In particular, it is important to emphasize the importance of comorbidity among various classes of mental

</table>
disorder in persons with intellectual disability. In doing so, it is also important to call attention to the problem of misclassification of various symptoms that may be common within presumed comorbid disorder categories. For example, it is important to distinguish symptoms of attention-deficit/hyperactivity, from symptoms of primary mania or secondary hypomania related to medication-related adverse effects as in behavioral activation. Another example includes differentiation of “ego-syntonic” symptoms involving repetitive stereotyped behaviors in autism spectrum disorder and characteristic “ego-dystonic” symptoms associated with obsessive-compulsive disorder. There is a need for evidence-based studies looking at comorbidity of mental disorders in persons with intellectual disability syndromes.

The outline below is useful largely from a review by Kalachnik et al. (1998) and Rinck (1998), as well as on the American Academy of Child and Adolescent Psychiatry (1999), and the Health Care Financing Administration (1997).

**Purpose of Pharmacotherapy.** Psychotropic drugs in persons with intellectual disability ought to be utilized to treat a diagnosed mental disorder toward the goal of maximizing the person’s quality of life. They should not be used merely to suppress a single, objectionable target behavior without regard to the effect on a person’s global adjustment, functioning, and quality of life. They cannot be used akin to inherent punishment, for staff convenience (as in under-staffed settings), in lieu of appropriate habilitative program (e.g., if such a program is unavailable or its quality is poor), or in dosages that interfere with a person’s quality of life (Rinck 1998, p. 52).

**Context of Pharmacotherapy.** The psychotropic drugs are to be used as part of a comprehensive treatment plan and habilitation programming designed and supervised by an interdisciplinary team of which the psychiatric clinician is an integral part. They should not be prescribed merely in brief “psychopharmacology consultation” or “medication review” session in isolation from other aspects of the treatment. Adequate number of psychiatrists ought to be trained for the care of persons with intellectual disability and the shortfall of qualified personnel should not justify use of proxy physicians to hand out prescriptions without requisite expertise or supervision even though it may meet minimum administrative guidelines for prescribing and may seem “cost effective” for institutional purposes.

**Prerequisite Steps for Pharmacotherapy.** Comprehensive psychiatric diagnostic assessment, following the guidelines described earlier (see also Figure 42–6), and resulting in a diagnosis of mental disorder is an essential initial step. Other steps include: the presence of a comprehensive treatment plan and evidence that less intrusive measures have not been effective (such as behavior modification, psychotherapies, and milieu supports); comprehensive evaluation to rule out medical conditions that could have caused the presenting symptoms; existence of a reliable system to collect behavioral data individualized to the particular patient that measures occurrence of symptoms considered to be an index of the person’s mental disorder. This should also provide reliable baseline data and a functional analysis of behavior that would assess the influence of immediate and more remote antecedents and consequences of patient’s behaviors and other symptoms. Finally, satisfaction of all relevant regulatory and legal requirements, especially obtaining informed consent of the patient and/or legal guardian.

**Follow-up on Drug Effectiveness.** A psychiatrist experienced in treatment of persons with intellectual disability and members of the interdisciplinary treatment team should ideally follow the patient’s progress regularly (at least quarterly), based on changes in individualized index behaviors, symptoms, general adjustment, functioning, and well-being. Presence of side effects and their findings should be communicated among the members of the team. Behavioral changes should be documented by reliable data. The follow-up should include a direct psychiatric interview and/or observation of the patient. The implementation of all aspects of the treatment program and not just the medications should be monitored and adjusted as needed to insure that medications are not used in lieu of, but concurrently with, a habilitation program. The medication should be tried at an effective dose for an adequate period of time. If there is no clear evidence of effectiveness it should be discontinued appropriately. It should be kept in mind that “ups and downs” are to be expected such as in reaction to environmental and physical stressors common in the lives of these patients. Medication effectiveness should therefore be judged by a pattern evident over a reasonable period of time and not by one-point observations. For the same reason, preset dosage schedules linking dosage changes to specific frequencies of index behaviors are impractical. Multiple medications should be tried only if there is evidence that a combination is known to be more effective than a single medication.

**Dose Reduction Discontinuation.** A trial dose reduction and possibly discontinuation should be regularly considered but should be implemented only if not contraindicated clinically. Discontinuation, if attempted, should be gradual, and it may need a prolonged period depending on the type of medication and expected withdrawal effects. It is essential that all involved caregivers be aware of the possibility of such effects and be ready to deal with them, rather than demand immediate cessation of the discontinuation trial; this is particularly important with atypical neuroleptics. As-needed (PRN) use of medications is best avoided to prevent unnecessary use, or limited to clear situations.

**Monitoring Side Effects.** Side effects should be monitored regularly through direct examination (especially important in the care of nonverbal persons), including laboratory tests, EKGs, tardive dyskinesia exams, as appropriate for the particular drug. Possible drug interactions should be monitored as these patients are often on multiple medications.

**Review of Classes of Psychotropic Medications.** Only issues specific to persons with intellectual disability are discussed here. For a full discussion, relevant other chapters in this book should be consulted.

The topography of available psychotropic medications for persons with mental disorders and intellectual disability is changing rapidly, as for all other populations. The traditional antidepressants (e.g., tricyclics) and antipsychotics (e.g., chlorpromazine, thioridazine) and neuroleptics
(e.g., haloperidol) that were once popular are recommended as a last resort. In the following discussion, only the salient usages of major groups of pharmacological agents are discussed.

**Stimulants and Nonstimulant Medications**

Generic short acting stimulants drugs such as methylphenidate and dextroamphetamine have long been proven effective in the treatment of attention-deficit hyperactivity disorder (Arnold et al. 1998). In persons with intellectual disability these agents have been studied primarily in children and adolescents with mild intellectual disability as well as pervasive development disorders. Their effectiveness in persons with significant intellectual disability is less certain. If a patient with intellectual disability is engaging in self-stimulatory behaviors, close observation or use of sample videotapes of behaviors at home or work setting behaviors can provide a useful backdrop to distinguish stereotypes and mannerisms from emerging tics or other abnormal movements (e.g., choreoathetoid movements).

As described earlier, establishing a diagnosis of comorbid attention-deficit/hyperactivity disorder in persons with intellectual disability is not straightforward, especially in those with severe intellectual disability, as the symptoms of inattention and poor impulse control, have to be assessed in the context of the patient's developmental level. Persons with intellectual disability with comorbid attention-deficit/hyperactivity disorder, regardless of their level of functioning (Ehlers and Gilberg 1993), may be eligible for treatment with stimulants. There is more evidence that persons with intellectual disability with a higher level of verbal and adaptive skills may respond better to stimulants. A number of long-acting stimulant agents (e.g., Adderall XR, Concerta, Metadate, Ritalin-LA, Focalin XR) and new atypical agents (e.g., Strattera (atomoxetine)) have been successful in targeting some individuals with attention-deficit/hyperactivity disorder. A concern with the use of stimulants in persons with intellectual disability in general has been the observation that they can lead to activation, with mood irritability, agitation, as well as sleep difficulties. Increased stereotypes, obsessive–compulsive symptoms and anxiety are also seen (Aman and Langworthy 2000).

Pharmacological studies of the treatment of attention-deficit/hyperactivity disorder symptoms in persons with intellectual disability with specific syndromic diagnoses such as Fragile X, Cornelia de Lange, Down and Williams have led to mixed findings. When using stimulants in young children, particular caution is advised in those with comorbid autism spectrum disorders. Nonetheless, as the relative index of safety of these medications is quite high, many clinicians have continued to initiate an empirical trial of a stimulant or nonstimulant agent under circumstances when clinically warranted.

**Antidepressants**

The principal uses of antidepressant medications, as in the general population, include treatment of depression as well as anxiety, panic, and OCD (Sovner et al. 1998). Selective serotonin reuptake inhibitors (SSRIs) are now first-line drugs because of their low side effect profile. Tricyclic antidepressants, principally the secondary amines such as desipramine, were once extensively used in the treatment of attention-deficit/hyperactivity disorder, especially if stimulants and clonidine were not effective, but these agents are no longer recommended in view of their potential cardiac effects related to unforeseen yet relatively rare conduction difficulties. The tricyclic antidepressants ought not to be excluded in special situations where the person with intellectual disability has not responded to SSRIs or venlafaxine and remains significantly depressed. Precipitation of activation, hypomania, and seizures by tricyclic antidepressants also present problems in the intellectual disability population, and careful baseline assessment is necessary. The SSRIs appear to be moderately effective in decreasing interfering symptoms of anxiety associated with transitions and sensory stimulation, as well as in diminishing repetitive thoughts, rituals, and preoccupations in ASD with or without intellectual disability.

The SSRIs are also effective, in part, for the treatment of symptoms of restlessness and hyperactive-impulsive behaviors if they are secondary to anxiety-related behaviors especially in nonverbal persons with intellectual disability. No single SSRI has been shown to be superior for this purpose. Early controlled trials with fluoxetine and fluvoxamine in adults with ASD with or without intellectual disability showed significant benefits over placebo, although a subsequent controlled trial of fluvoxamine in children and adolescents revealed a lower response (McDougle et al. 2000). An open label study using low-dose fluvoxamine reported a response in only 17% of individuals (Martin et al. 2003). SSRIs are used in practice to treat depression, anxiety, and obsessive, compulsive and ritualistic behaviors (Steingard et al. 1997). There are a few studies, mostly case reports, that have suggested that selective serotonin reuptake inhibitors might be helpful in reducing self-stimulatory and SIB, although the improvement might be short-lived and pharmacotherapy of SIB remains a major challenge (King 2000).

**Antipsychotics**

The use of both the traditional and atypical antipsychotic drugs in persons with intellectual disability is the same as that for the general population—primarily for the treatment of associated psychotic symptoms or as an emergency treatment of dangerous and disruptive-aggressive behavior. The main target symptoms potentially responsive to atypical antipsychotics include severe tantrums and disruptive behaviors, agitation, aggressive behaviors, comorbid major affective disorders, and, more rarely, psychosis. Unfortunately, despite the recent success of using low dose atypical antipsychotics, there is an important legacy of abuse of traditional antipsychotics in persons with intellectual disability especially in institutional settings. It is important not to assume that a person by virtue of having intellectual disability also suffers from schizophrenia or schizoaffective disorder, leading to persistent use of antipsychotic agents. Both the traditional and atypical antipsychotics have long been used for “off-label” indications as mentioned above including aggression, destructiveness and disruptive behaviors. If an antipsychotic medication is effective in alleviating such behaviors, it does not necessarily mean that the person with intellectual disability suffers from a comorbid psychotic disorder. Nevertheless, there has been a tendency to justify such “off-label” use by perhaps ascribing a non-specific
weight gain of 2.7 ± 2.9 kg, as compared with 0.8 ± 2.2 kg
SIB. Risperidone therapy was associated with an average
well-tolerated for the treatment of tantrums, aggression, or
the safety and efficacy of risperidone in 101 children and
of a National Institutes of Health multisite trial, looked at
Research Units in Pediatric Psychopharmacology (RUPP)
been two double-blind placebo controlled studies. The
nia or bipolar disorder who otherwise have not responded
persons with intellectual disability (including risperidone, olanzapine,
quetiapine, aripiprazole, among others) also pose particular
difficulties. If a trial is indeed justified, extended observa-
tion by trained staff and close monitoring of liver function
tests, EKG, and fasting blood sugar and lipids are necessary.
Individuals with intellectual disability are more vulnerable
to most of the side effects of these agents. They are gener-
ally unable to communicate subjective feelings of sedation
or restlessness (akathisia) due to their cognitive limitations
and difficulties in communication. Furthermore, drowsiness
associated with treatment and these agents have a propor-
tionately greater negative effect on learning and on general
level of activity in persons with intellectual disability than
among typical individuals. A common mistake is to confuse
withdrawal symptoms or increased extrapyramidal symp-
toms upon discontinuation, leading to resumption of the
medication. Weight gain remains as the most common side
effect of atypical antipsychotic agents in persons with intel-
lectual disability, as these individuals are especially prone to
excessive eating, poor dietary regulation of food content,
lack of exercise, and other lifestyle issues related to their
disability. The secondary effects of weight gain in terms of
cardiovascular function, elevation of blood sugar and lipids
are also of considerable concern. Nutritional intervention is
recommended for individuals who demonstrate significant
weight gain during treatment or who are overweight at the
outset. A full lipid panel with fractionation of cholesterol
are recommended annually, with quarterly fasting total trig-
lyc erides and cholesterol during the first year of treatment.
Fasting blood sugar levels, liver function tests, prolactin,
and electrocardiograms should also be monitored.

The discontinuation of antipsychotic medications
should be gradual and slow to minimize side effects from
withdrawal, including behavior problems such as irritability,
insomnia, SIB, and aggression (Guatieri et al. 1986).

There are case reports of successful use of clozapine in
persons with intellectual disability and comorbid schizophre-
ia or bipolar disorder who otherwise have not responded
to other mood-stabilizing agents. The need for weekly blood
tests may be a problem in less than cooperative persons.

Risperidone is the most studied among the major
atypical antipsychotic medications among children and
adolescents with ASD (McDougle et al. 1998). There have
been two double-blind placebo controlled studies. The
Research Units in Pediatric Psychopharmacology (RUPP)
Autism Network (McCracken et al. 2002), funded as part of
a National Institutes of Health multisite trial, looked at
the safety and efficacy of risperidone in 101 children and
adolescents with autism. Risperidone was effective and
well-tolerated for the treatment of tantrums, aggression, or
SIB. Risperidone therapy was associated with an average
weight gain of 2.7 ± 2.9 kg, as compared with 0.8 ± 2.2 kg
with placebo (P < 0.001). Increased appetite, fatigue, drow-
siness, dizziness, and drooling were more common in the
risperidone group than in the placebo group (P < 0.05 for
each comparison). In two thirds of the children with a posi-
tive response to risperidone at eight weeks, the benefit was
maintained at six months. Similarly, a Canadian study by
Shea et al. (2004) involving 79 subjects reported efficacy of
risperidone in autism as well as the broader pervasive devel-
mental disorder phenotype. By alleviating the interfering
behavioral problems, the atypical antipsychotics can allow
persons with ASD in the presence of or absence of intel-
lectual disability to be more amenable in terms of improved
social interactions. In low-dosage ranges, the atypical antip-
sychotics are rarely associated with extrapyramidal symp-
toms or tardive dyskinesia. Nevertheless, there are higher
rates of irritability, serious aggressive behaviors, and SIB in
children with autism in the presence of increasing degree of
intellectual disability, making it highly likely that medica-
tion will be more likely to be used in the group with autism
in the presence of intellectual disability. This is an impor-
tant ethical concern, that is, behavior control in a more vul-
nerable group. Criteria for discontinuation and long-term
risk of use of risperidone ought also to be considered in this
group. On the other hand, vulnerable children ought not
to be deprived of the benefit of psychotropic medications,
(see review: Yan and Munir 2004). However, irrespective of
these concerns, psychotropic medication cannot be a sole
means of management of undesirable behavior, especially
for the more severely compromised children.

SIB seen in ASD and intellectual disability are poorly
responsive to pharmacological interventions, including
atypical neuroleptics.

Anticonvulsants
Persons with intellectual disability experience both clinical
or subclinical seizures at a much higher risk than in
the general population and, therefore, should have a full
baseline neurological assessment. Significant clinical and
subclinical seizures, if left untreated, can lead to deleterious
effects. As seizures can emerge at any time, they should be
ruled out as possible contributory factors for any change
in behavior (tantrums, irritability, and agitation), sleep, and
regulatory functions. There is also an increased incidence
of newly onset seizures in seizure-free individuals with
ASD as they progress through puberty and adolescence.
Pharmacological treatment with sodium valproate has
been used in particular children with ASD who present
with a developmental regression in milestones or seizures,
sometimes in the context of Landau–Kleffner syndrome.
Sodium valproate has also been used with modest success
in the treatment of secondary symptoms of hypomania
in association with irritability, silly or elated moods, tem-
per outbursts, and agitation. Clinicians have been apt to
translate their experience from sodium valproate to other
anticonvulsants; lamotrigine has not been as effective, and
the most commonly used anticonvulsants after valproate
for targeting behaviors have been carbamazepine and
oxycarbamazepine.

Alpha agonists
The use of clonidine hydrochloride and guanfacine hydro-
chloride can effect a modest reduction in impulsivity,
hyperactivity and irritability (McDougle et al. 2003, Jaselskis et al. 1992). Drowsiness has been reported as a main side effect and often can target sleep difficulties commonly reported in young children with autism and related disorders. Clonidine is a presynaptic alpha-2-adrenergic agonist more commonly used in the treatment of attention-deficit/hyperactivity disorder in children and adolescents. There also have been case reports of clonidine being effective in the treatment of persons with fragile-X associated with disruptive behaviors (Hagerman et al. 1998). Again, drowsiness, hypotension, bradycardia, and less commonly skin reaction (from topical patch) need to be monitored. Many of these side effects can be mitigated by use of a moderate dose to begin with, especially since persons with intellectual disability are less likely to report feelings of drowsiness. Clonidine has also been reported to be effective to some extent in the treatment of akathisia related to neuroleptic drug withdrawal (Sovner 1995).

Antianxiety Drugs
Benzodiazepines have been used for alleviation of anxiety, but their side effects such as paradoxical rage reactions, adverse effects on cognition, and serious withdrawal symptoms argue against their chronic use, and a trial of a SSRI might be preferable. Occasional use might be helpful in emergency situations in which extreme anxiety is present as well as in preparation for anxiety-inducing procedures as well as other special situations that may require sedation such as air travel. Nevertheless, if benzodiazepines are to be recommended in such circumstances they ought to be tried before under controlled circumstances to predict undue effects such as disinhibition that may make the situation worse.

Benzodiazepines are still used for the treatment of general anxiety and panic disorders, but usually only when there is no response to antidepressants. There is still a fair amount of combined use of neuroleptics and anxiolytics, especially in institutionalized persons with history of aggression. However, this may lead to significant CNS depression and the benzodiazepine use might actually lead to disinhibition (Werry 1998). Therefore, prolonged use of anxiolytics to control undesirable behaviors is generally not recommended (Werry 1998). As with other medications, comprehensive diagnostic assessment is a prerequisite to the use of anxiolytics. In particular, environmental anxiety-provoking factors have to be ruled out and, if present, have to be dealt with in addition to pharmacological means if these are used. Buspirone, a non-sedating and non-tolerance forming anxiolytic agent with a short half-life, has also been used in treatment of persons with intellectual disability experiencing symptoms of anxiety and restlessness but its usefulness has not been substantiated.

Lithium
The use of these agents in persons with and without intellectual disability is again similar. Lithium carbonate, the original mood stabilizer, was shown effective for bipolar disorders, mixed affective states with mood lability, as well as affective disorders with underlying CNS dysfunction in persons with intellectual disability dating back to the 1970s. However, Lithium was noted to have considerable side effects, especially in circumstances lacking close oversight of lithium blood levels, thyroid function tests and renal function. In addition, monitoring regular blood drawings is difficult in individuals who might otherwise be less than cooperative. Lithium carbonate has therefore been gradually, but not altogether, supplanted by increasing acceptance of anticonvulsants, including valproic acid, carbamazepine, more recently oxycarbamazapine, as well as other agents such as topiramate and lamotrigine, although the latter also requires close oversight with respect to hematological complications and risk of Steven Johnson syndrome. Currently, the primary use of lithium is for the treatment of comorbid bipolar disorder and for augmentation of antidepressants. There are also studies indicating to the effectiveness in some individuals with impulsive aggressive behavior but again caution is needed not to engage in treatment of individual target behaviors but to develop a systematic behavioral management approach (Craft et al. 1987). As seizures are frequently associated with intellectual disability, these drugs offer a parsimonious way of managing both the potential for seizures as well as behavioral problems associated with comorbid mental disorders.

Other Psychotropic Agents
Propranolol and other beta-adrenergic blockers have been used following the earlier reports on the beneficial effects in rage attacks associated with a definite pathological brain condition (Williams et al. 1982). They have been tried extensively in all kinds of aggressive behavior, often with mixed or poor results. Depression might be a side effect of these agents, leading to reduction in the person’s functioning, even if the aggressive behaviors might appear to improve, because of apathy induced by the drug. They may be also effective in the treatment of anxiety, especially its somatic symptoms, and for akathisia related to neuroleptic drugs.

Naltrexone, an oral antagonist of endogenous opioid receptors, has been tried in a number of studies in cases of severe SIB, following some case reports of earlier successes with a similar agent, naltrexone, which had to be administered parenterally. It appears that it is effective in 35-70% of cases, at least for a short time (Sandman et al. 1998).

Other Treatments
For many years there have been reports of beneficial effects of a variety of treatments, especially in children with PDD, Down syndrome, and fraX syndrome. These treatments include various nutritional supplements, vitamin supplements (such as megavitamins, various combinations of vitamins, minerals and enzymes, B6, B12 with magnesium, folic acid, etc.), and dietary interventions (as in restriction of food additives, gluten, casein, or yeast). Often these approaches generate considerable excitement among families. Nevertheless, there is a need for replicated well designed studies for assessing CAM (American Academy of Child and Adolescent Psychiatry 1999, Singh et al. 1998). The situation may be difficult to oversee as the use of CAM can be implemented by many families without consultation of their physician. However, one should bear in mind that persons with developmental disabilities in general, and especially those with autism and PDD, may have unusual eating habits resulting in highly idiosyncratic and restricted diets. Therefore, in such cases a nutritional consultation may be advisable. If a deficiency is found, an appropriate
supplementation and correction of dietary habits is of constant need. One example is zinc deficiency associated with picket, which was shown to disappear or decrease after treatment with 100 mg of chelated zinc for 2 weeks (Lofts et al. 1990). Although not an absolute contraindication, electroconvulsive therapy (ECT) has fallen into disuse in persons with intellectual disability as a direct consequence of past inappropriate uses, need for informed proxy consent and strict certification requirements. Occasional case reports of its successful use can still be found in the literature.

**Psychosocial Interventions**

**Programmatic and Educational Approaches**

The goal of these interventions is to provide a proper living and programmatic environment. For instance, certain persons easily become over stimulated, anxious, and disruptive in large and noisy workshop settings; for those individuals arranging for a smaller and quieter workroom is preferable, but certainly may prove more involved than the temptation to prescribe a psychotropic agent. The vocational and educational program for a person with intellectual disability should be individualized and the focus ought to be on developing the person’s strengths and providing an opportunity for his or her ultimate success in adapting to situations and feeling valued and productive. In turn, this is likely to lead to results such as an improvement in self-image. Many persons with severe intellectual disability are placed in prevocational training indefinitely, for example, screwing or unscrewing nuts and bolts, although no one expects them to ever be employed on an assembly line. They often engage in a struggle with caregivers because of their noncompliance and may resort to aggression, which leads to removal for a “time out” and thus avoidance of a boring task. Creating more suitable tasks is now becoming the norm—these now involve making rounds to collect or deliver materials in schools, hospitals, nursing homes, or hotels—might be more interesting and appropriate. This may involve stacking shelves in a supermarket, assisting in meals-on-wheels; often the social interactions the persons with intellectual disability experience in such settings also prove more meaningful. Functional analysis of behavior is an invaluable guide to these interventions. As discussed previously, such approaches should be explored prior to resorting to use of medications for disruptive behaviors.

**Psychotherapies**

Both individual and group psychotherapies have been effectively used in persons with intellectual disability dating back to the 1930s (Stacey and DeMartino 1957), and there continue to be many case reports on their success. Psychotherapy in this population is more akin to work with children, inasmuch as in both situations the therapist has to adapt the techniques to the developmental needs of the patient. It is also important to emphasize at the outset that the treatment ought to be guided by the patient’s needs and responses and not by the therapist’s theoretical orientation. Detailed techniques that can be used have been described (Szymanski 1980a, Szymanski and Rosefsky 1980). The indications are: the presence of concerns and conflicts, especially about one’s situation and self-esteem; impairments in interpersonal skills or stressors related to relationships or losses; and other emotional problems known to improve through supportive psychotherapy such as need to prepare for important changes and transitions. The prerequisites include communication skills permitting a meaningful interchange with the therapist, an ability to develop even a minimal relationship, and the availability of a trained, experienced, and unprejudiced therapist who is comfortable working in a team setting. From applicable literature, Reiss and Benson (1985) summarized the guidelines for psychotherapy in this population, which include the following:

1. Appropriate goals should be set and should be reconciled with the expectations of the caregivers, the therapist, and the patient. Common goals include improvement in self-image and impulse control, learning to express feelings in a socially appropriate manner, and understanding in a constructive manner one’s own disabilities and strengths.
2. The verbal techniques should be adapted to the patient’s language and cognitive level, and the nonverbal ones should be age appropriate.
3. Limits and directive nature should be used as needed: nondirective therapy might lead to a patient’s confusion. The therapist has to be active (supportive but not paternalistic), has to use herself or himself liberally as a treatment tool, and has to be able to focus on the immediate reality rather than just intellectualize.
4. A mix of techniques, for example, cognitive psychotherapy and behavior modification, may be required.
5. As in all treatment modalities, the therapist should be involved in all aspects of the patient’s program and collaborate with other providers and with the family.

Group psychotherapy might be particularly effective in helping patients handle issues related to the understanding of their own disability and learn social skills because of the peer support the group offers (Szymanski and Rosefsky 1980). In general, therapy should be seen as a cognitive learning process, using the therapist’s support and leading patients to the acquisition of understanding and necessary skills, both of concrete behaviors and of handling one’s own emotions. Group psychotherapy should be differentiated from group counseling which usually is educational in nature, focused on a specific subject (e.g., sexuality education), and does not have to be conducted by a mental health professional with a therapeutic goal and plan.

**Behavioral Therapy**

Behavioral techniques are described elsewhere in this chapter and their application in persons with intellectual disability has been long-standing (Jansen 1980). Detailed functional analysis is a prerequisite. This treatment should optimally use rewards which should be age appropriate, preferably social, and the frequency of rewarding should be adapted to a person’s cognitive level, so that he or she can understand why they are given. Consistency and generalization among different settings are essential. Thus, if such techniques are successfully used at the school, the family or other caregivers should be trained to use them at home as well. The focus should not only be on elimination of objectionable behaviors but on teaching appropriate replacement behaviors.
Aversive techniques involving active punishment (electric shocks, spraying of noxious substances into a person’s face) are not to be used except in a few controversial settings. There is a professional consensus that these techniques should not be used at all, or only when all other techniques have failed and the patient’s behavior poses severe danger to herself or himself or to others (such as intractable SIB). Even then, these techniques should be used only if proved effective and for a limited time.

**Psychiatrist–Patient Relationship: Models of Delivery of Psychiatric Services**

The psychiatric care of persons with intellectual disability has often followed a path different from the care provided to the general population. A common service model has been the medication clinic, in which the psychiatrist is given little, if any, time to examine the patient and to interview the caregivers. Instead, behavioral information, which is often brief and sketchy, is presented by caregivers and focuses primarily on disruptive behaviors. The psychiatrist is expected to prescribe medications and has no voice in, or knowledge of, other interventions that might be used. In some cases, the psychiatrist does the actual prescribing; in others, the psychiatrist serves as a consultant to primary physicians who may or may not follow the recommendations given. This model is obviously inadequate, even if there is another professional providing psychotherapy or behavioral therapy. It also exposes the psychiatrist to legal responsibility (Woodward et al. 1993). This model has been used in institutions, especially to save on the expense of having a staff psychiatrist to provide adequate services.

The proper psychiatric care of persons with intellectual disability is actually more time-consuming than the care of persons without intellectual disability because of the multi-modal nature of the treatments described previously. To understand a patient’s clinical presentation and provide the input necessary for all relevant aspects of treatment, the psychiatrist has to have adequate time to interview all involved caregivers, observe and interview the patient, make a home or program visit if necessary, and discuss the recommendation with all involved. Thus, an interdisciplinary team approach is essential. It might not be realistic for all patients seen in the community, but it should be followed in all treatment-resistant cases and in residential facilities where, as a rule, there are more difficult patients (Szymanski et al. 1980, Szymanski and Leaverton 1980). In most cases in the community, if a team forges a good working relationship and regular communication, exchange of information and coordination via e-mail or telephone might be sufficiently productive. Some states have developed successful models of such coordinated care (that provide for health, housing, vocational and social services) for persons who have both intellectual disability and mental illness (Polgar et al. 2000). In all situations, psychiatrists will best use their knowledge and training in biological and behavioral aspects of medicine to help other professionals synthesize the biopsychosocial aspects of a patient’s clinical presentation and treatment program.

**Conclusion**

The World Health Organization (2001) report on caring for persons with mental disorders has emphasized the disproportionately high global burden of intellectual disabilities. The treatment gap in diagnosis and interventions among persons with intellectual disability remain unmet worldwide (Erol et al. 2005). The National Research Council (2001) on educational interventions in developmental disabilities had identified seven key areas for improvement that include: (1) early diagnostic assessments, (2) understanding of the effect on families and role of families in care, (3) development of appropriate goals for educational and rehabilitation services, (4) salient characteristics of effective interventions and educational services, (5) development of public policy initiatives to ensure access to educational and rehabilitative programs, (6) improvement in the training of professionals, and (7) enhancement of future research. Development of requisite expertise in the training and education of both adult and as well as child and adolescent psychiatrists in caring for the mental health needs of persons with intellectual disability is also an important critical concern. Finally, parent-guided and both publicly and privately supported organizations are particularly useful in developing “actionable” steps to improve outcomes in this population. This has proven to be very important in raising public awareness and garnering research-funding support in this area.

Chapter 42 • Childhood Disorders: Intellectual Disability 745
For children and adolescents, school is their “workplace.” Successful school performance is essential for psychological growth and development. Social competency and social skills are developed and then shaped within the family and in the school but practiced and mastered in the school. The development of a positive self-image and self-esteem is based on successes in school. Feedback from the school concerning academic performance and social interactions influences the parents’ image of their child or adolescent. Thus, if something interferes with success in school, the impact will affect the emotional, social, and family functioning of the child and adolescent.

Academic performance requires the integrated interactions of the cognitive, motor, and language functions of the brain. As detailed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR), if brain dysfunction results in cognitive difficulties, it is called a learning disorder; in motor difficulties, a motor skills disorder; and in language difficulties, a language disorder. Chapter 44 reviews the communication disorders, including language disorders.

Key for the mental health professional is the understanding that the underlying neurological dysfunctions that result in learning disorders and motor skills disorder have an impact on more than academic performance. These disabilities affect every aspect of the individual’s life during each stage of psychosocial development (Silver 1989, 2006). Of further importance is our knowledge of a continuum of neurologically based disorders that are often found together. Part of this continuum includes learning disorders, motor skills disorders, and language disorders. If a child has one of these disorders, there is a high likelihood, possibly up to 50%, that he or she will also have one or more of other disorders to be discussed later in this chapter.

**Definitions**

Public education laws use the term learning disabilities. DSM-IV-TR uses the terms learning disorders and motor skills disorder. It is helpful to understand that these terms reflect the diagnostic system used but refer to the same set of difficulties.

Public school systems use the Federal definition, based on the initial public law, PL 94–142, The Education for all Handicapped Children, and its revisions. The most recent revision is PL 108–446, the Individuals with Disabilities Education and Improvement Act (IDEA 2004). In this law, a learning disability is defined by inclusionary and exclusionary criteria:

Specific learning disabilities means a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write,
spell, or to do mathematical calculations. The term includes such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. The term does not include children who have learning problems which are primarily the result of visual, hearing, or motor handicaps, or mental retardation, of emotional disturbance, or of environmental, cultural, or economic disadvantage.

The Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) was the first medical diagnostic system to refer to these problems. In DSM-III, the concept of learning disabilities was not used. The focus was on the areas of academic difficulty, and the term used was academic skills disorders. The specific types of disorders reflected general areas of difficulty: developmental arithmetic disorder, developmental expressive writing disorder, and developmental reading disorder. There was no reference to motor disorders. These disorders were listed, along with language disorders, under the broad category of specific developmental disorders. This focus on developmental disorders reflected the facts that they were found in children and adolescents and that they greatly affected all aspects of development. This term did not reflect the reality that, for most persons, these disabilities will last throughout their lives. The Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) maintained the focus on specific developmental disorders and on the same three general areas of difficulty. However, motor skills disorder was added.

In DSM-IV and DSM-IV-TR, the term academic skills disorders was changed to learning disorders. Three subtypes of learning disorders are identified: reading disorder, mathematics disorder, and disorder of written expression. Only developmental coordination disorder is listed under the category motor skills disorder.

Diagnosis

It is important to understand that the criteria used in DSM-IV-TR as well as the criteria used by school systems is based

Chapter 43 • Childhood Disorders: Learning and Motor Skills Disorders

Disorder of Written Expression

A. Writing skills, as measured by individually administered standardized tests (or functional assessments of writing skills), are substantially below those expected given the person’s chronological age, measured intelligence, and age-appropriate education.

B. The disturbance in criterion A significantly interferes with academic achievement or activities of daily living that require the composition of written texts (e.g., writing grammatically correct sentences and organized paragraphs).

C. If a sensory deficit is present, the difficulties in writing skills are in excess of those usually associated with it.

2. Evidence of a disorder in one or more of the basic psychological processes required for learning. A psychological process is a set of mental operations that transform, access, or manipulate information. The disorder is relatively enduring and limits ability to perform specific academic or developmental learning tasks. It may be manifested differently at different developmental levels.

3. Evidence of academic achievement significantly below the student’s level of intellectual function (a difference of 1.5–1.75 standard deviations between achievement and intellectual functioning is considered significant) on basic reading skills, reading comprehension, mathematical calculation, mathematical reasoning, or written expression.

4. Evidence that the learning problems are not due primarily to other handicapping conditions (i.e., impairment of visual acuity or auditory acuity, physical impairment, emotional handicap, mental retardation, cultural differences, or environmental deprivation).

In the 2004 revision of the Individuals with Disabilities Education Act, an alternative to the above-described discrepancy model for assessment is proposed. It is referred to as the “Response to Intervention” model. This assessment uses a three-tier approach to helping students having difficulty learning. Formal testing may be done after Tier 2 interventions; however, the U.S. Department of Education Rules and Regulations for the revised law suggest but do not require that formal testing be done.

If a student shows difficulty learning, he or she enters Tier 1. Here, high-quality instructions and behavioral supports are provided by the teacher in the general education

Learning Disorder Not Otherwise Specified

A. This category is for disorders in learning that do not meet criteria for any specific learning disorder, for example, a disorder in which spelling skills are substantially below those expected given the person’s chronological age, measured intelligence, and age-appropriate education.

B. The disturbance in criterion A significantly interferes with academic achievement or activities of daily living.

C. The disturbance is not due to a general medical condition (e.g., cerebral palsy, hemiplegia, or muscular dystrophy) and does not meet criteria for a pervasive developmental disorder.

D. If mental retardation is present, the motor difficulties are in excess of those usually associated with it.
The evaluation of a child or adolescent with academic difficulties and emotional or behavior problems involves a comprehensive assessment of the presenting emotional, behavior, social, or family problems as well as a mental status examination. The psychiatrist should obtain information from the child or adolescent, parents, teachers, and other educational professionals to help clarify whether there might be a learning disorder or motor skills disorder and whether further psychological or educational studies are needed. Descriptions by teachers, parents, and the child or adolescent being evaluated will give the psychiatrist clues that there might be one of the learning disorders or a motor skills disorder.

The DSM-IV-TR criteria cover major skill areas: reading, mathematics, and writing. When assessing a student who is struggling in school, it is helpful to understand the many forms each of these skill difficulties might take. Later, a developmental model for understanding school skill expectations will be discussed, allowing the clinician to assess if the level of reading is at expected grade level or not.

Children who experience problems in reading might have difficulty with the first task in learning to read, that is, putting sounds and letters together and decoding the word. They might read each word in a disjointed manner, knowing a few words on sight and struggling with unfamiliar words or they might have difficulty with visual tracking, skipping words or lines. Others might have difficulty with the next skill needed in reading. They can decode the words but they have difficulty comprehending what they have read. Others might have difficulty with yet the next skill needed in reading. They can decode and comprehend but have difficulty retaining what they have read (referred to as reading fluency). They get to the end of the chapter and do not retain what they read. Children with mathematical difficulties may have a problem recognizing numbers and not confusing subtle differences in shape (e.g., 6 and 9). The earliest skills involve learning what is called the “base 10” concept (all number systems are in units of 10) and what is referred to as the “conservation of numbers” (i.e., numbers are fixed entities; one cannot create a number from nothing or make a number disappear). Later, one must learn multiplication and division, then fractions and decimals. These skills are built on to learn higher math concepts. For each of these steps in learning, some students might have difficulty remembering facts (e.g., the times tables) and some might have difficulty retaining and applying these facts. Some have the ability to do calculations in their head but have difficulty when they must write out and show the steps involved in solving the problem. They might make careless errors or have problems with visual–spatial tasks or with sequencing the information. Some might have difficulty shifting from one operational concept to another.

Children who have difficulties with writing may have a problem with the fine motor skill of handwriting, referred to as a graphomotor problem. They grasp the pencil or pen differently and might hold tightly. They might write slowly and their hand gets tired. Printing might be preferred over cursive. Separate from this motor problem, students might have difficulty with written language—spelling, grammar, punctuation, capitalization. Still others might have difficulty organizing their thoughts and getting them onto the paper.

In addition to reading, writing, and math difficulties, students might struggle with problems of organization and
executive function. Organization problems might impact on keeping track of their materials. They lose, forget, or misplace their papers, notebooks, books, and other materials. They might leave items at home when they go to school or items in school when they come home. Often, these students have equal difficulty keeping track of their personal belongings (jackets, pencils) and organizing their bedroom. Organizational problems can also involve the ability to organize information in meaningful way in order to learn it or to know what information is important to know.

Some may have difficulty organizing the information in their head when they must answer a verbal or written question. Executive function refers to the ability to think through a task, establish the steps needed to solve the task, start the process, make modifications in these steps later if needed, and complete the task in a timely way. Students with these problems struggle to start complex tasks and often have difficulty with time planning.

Children and adolescents with a developmental coordination disorder may show evidence of fine motor or gross motor difficulties. The fine motor problems might result in difficulty with cutting and pasting, learning to button, zip, or tie, holding a pencil or pen when writing, or controlling eating utensils, resulting in a preference to eat with fingers or a spoon. Thus, it is important for the clinician to realize that the child with a handwriting problem might have other fine motor problems that impact on his or her life. Gross motor problems might result in difficulty with coordination when walking, running, jumping, or climbing. These motor problems might include visual-motor difficulties (using visual input to tell muscles what to do) or visual spatial problems (knowing where one is in space, bumping into things).

Within the educational system individuals with developmental coordination disorder in which the motor problem has a sensory component (e.g., tactile, vestibular, proprioceptive) are considered to have a Sensory Processing Disorder. This disorder is based on concepts about the relationship between the neurological processes, behavior challenges, daily life skills, and sensory–motor abilities (Ayers 1972, Bundy and Murray 2002, Koomar and Bundy 2002). If one or more sensory systems are not processing properly, the result is sensation that is not properly modulated or discriminated or the responses are not properly graded to the sensory input. Three processing systems relevant to developmental coordination disorder are the tactile system, the vestibular system, and the proprioceptive system. Visual perception is an essential component of sensory integration as well.

Ocational therapists are trained to diagnose and to treat this disorder. The tactile system involves the sense of touch and the stimulation of skin surfaces. Some children will have problems with tactile defensiveness characterized by over-responsiveness to tactile stimuli that is perceived as neutral by others. These children experience discomfort when touched by another person especially if the touch is unexpected. For example, infants with tactile defensiveness often resist being held or fed. Older children may complain about tags on the back of their shirts, seam in socks, or other rough surfaces. It is not unusual for children to respond aggressively or by withdrawal (e.g., “fight or flight” responses), when they are accidentally jostled while in line.

The vestibular system allows individuals to detect motion. The vestibular system allows children to know where their body is in space and where their head is in relation to gravity. Children with vestibular disorders fall frequently and may be terrified of activities in which their feet are required to leave the ground. They often have difficulty mastering riding a two-wheel bike or going down stairs with one foot on each step. Some children with vestibular impairments will have weak upper trunk muscles, poor core stability, and low endurance.

The proprioceptive system processes incoming messages from the muscles or joints. If the fine motor proprioceptive system is impaired, the result might include difficulty with such fine motor skills such as coloring, cutting, writing, buttoning, zipping, tying, and controlling eating utensils. If the gross motor proprioceptive system is impaired, the child might have difficulty with running, jumping, skipping, and climbing.

The Educational Curriculum and Diagnosis
Professionals working with children and adolescents understand the importance of knowing developmental stages. Whether one is assessing for psychological or social levels of behavior or cognitive, motor, or language abilities, it is difficult to determine if someone is at age/grade level, delayed, or advanced in any psychological expectation without knowing the age/expected norms.

This need is equally essential when assessing a child or adolescent with academic difficulties to determine if he or she has a learning or motor skills disorder. What should the student be able to do in first grade, third grade, fifth grade, middle school, high school? The answer is based on a knowledge of cognitive, motor, and language development and the curriculum demands of the school system. Educational curriculum is based on knowledge of brain development and, thus, cognitive, language, and motor development.

Reading. In preschool, students are expected to learn two basic requirements for learning to read. First is rapid letter recognition and second is the ability to know what sound goes with each letter. These letters are called graphemes and the sounds are called phonemes. In first grade, the student learns to put the correct phoneme to the correct grapheme and “sound out” words. After a word has been sounded out frequently, most students recognize the word as a whole and can read it without the need to decode (sight reading). In second grade, these skills are developed further, leading to increased speed. Students who struggle to learn these skills often end up in the lower reading groups. Third grade brings a new set of demands. The assumption is that the student can now read. The focus shifts to knowing what has been read, reading comprehension. Books are assigned and the student reads them. Gradually, through third and fourth grade, the length and complexity of the books increase. By the end of fourth grade it is assumed that the student can read, comprehend, and retain what they have read. These skills are critical because by fifth grade and beyond the assumption is that one can read, comprehend, and retain. The focus shifts now to using these skills to learn subject content. The subject taught (history, literature, science) becomes the focus.

Writing. In preschool, students start to learn the letters of the alphabet and numbers. They learn to recognize each and to form each. During first and second grade, the focus
is on forming each of these symbols correctly and on the line. Capitalization and punctuation facts are introduced. Initially, spelling might be “creative;” however, soon, correct spelling is expected. Concepts of grammar are introduced.

By third grade, it is assumed that the student can write with basic spelling, capitalization, and punctuation. Grammar skills are improved as well as the student’s ability to get his or her thoughts organized and onto the page. Then, in third grade the focus shifts from “can you write” to “what have you written;” for example, book reports, journals. These skills are improved in fourth. By fifth, the assumption is that writing skills are in place. The focus shifts from using writing skills to learning subject content. Thus, the focus is on the subject taught with the assumption that the writing skills are there.

Mathematics. In preschool, kindergarten, even in first grades students are taught the two basic concepts described earlier in this chapter, base ten and conservation of numbers. In third grade, multiplication and division skills are added. By fourth, multiplying and dividing three and four digit numbers, fractions, and decimals are added. By fifth grade, these skills are assumed to be present. They are used to introduce higher-level math such as algebra and beyond.

Organization and Executive Function. These skills are introduced and taught in first through fifth grades. Such skills include organizing one’s notebook, backpack, and papers as well as keeping track of assignments and when assignments are due. In middle school, there is an increased expectation that the student will be able to organize increasing amounts and complexities of information and produce fuller answers to questions as well as to write more elaborate papers and do projects. Teachers help students learn how to do these skills and provide a structure for learning these skills. By high school, the teacher’s assistance and support may be removed. The student is expected to function independently. Thus, some students with organizational problems manage through middle school then have significant difficulties in high school.

Given the above academic and developmental information, it is possible to ask parents, children, and adolescents a series of questions, designed like a systems review, to screen for possible learning or motor disorders. These questions can be asked in a brief period of time and provide clinical clues suggesting a possible problem with skills or with underlying processing problems. Like any other “systems review,” the answers must be assessed based on the student’s age and grade level (see Table 43–2).

Differential Diagnosis
The presenting problem is academic difficulty. The differential diagnostic process must clarify the reasons for the academic difficulty. A “decision tree” for academic difficulties developed by Ostrander and Silver is useful for exploring all of the possible reasons for such difficulties (Figure 43–1).

When the presenting problem is academic difficulties, there are three principal areas of inquiry concerning the factors contributing to the student’s difficulties. The first involves considerations that are related to the child’s or adolescent’s psychiatric, medical, or psychoeducational status. The second area of inquiry is family functioning. The third area to explore involves the environmental and cultural context in which the student functions.

Evaluation of the Child or Adolescent
Difficulties in academic performance of children or adolescents can be related to a range of psychiatric, medical, or cognitive factors. To best determine the primary source of academic difficulties, the evaluation should involve a comprehensive examination of these areas. The psychiatric evaluation should clarify whether there is a psychopathological process. If one is present, it is useful first to determine whether the problems relate to a disruptive behavior disorder, including attention-deficit/hyperactivity disorder (ADHD), or to another psychiatric disorder. In particular, the disruptive behavior disorders have high comorbidity with academic difficulties. A full assessment should clarify whether a disruptive behavior disorder is causing the difficulty with academic performance or is secondary to this difficulty. Disruptive behavior disorders can result in the student being unavailable for learning or being so disruptive as to require removal from a general education setting. However, equally possible is that the frustration and failures caused by a learning disorder or motor skills disorder can be manifested by a disruptive behavior disorder. In some cases, the disruptive behavior disorder coexists with learning or motor skills disorder and the relationship is less clear. Children with ADHD have particular difficulty maintaining attention, and possibly with processing information. As a result, the same variables that have an impact on their attention might also have an impact on their ability to learn. In such instances, they may have a learning disorder and ADHD.

Internalizing disorders such as depression or anxiety may result in an uncharacteristic disinterest in or avoidance of school expectations. If one of the internalizing disorders is present, it is important to clarify whether it is a comorbid condition or secondary to the frustrations and failures resulting in an academic difficulty.

Other psychiatric disorders will impact on availability for learning or on academic performance. The clinician must clarify if the primary problems relate to a pervasive developmental disorder or a psychotic disorder. Substance use, misuse, and abuse may be the primary cause for the academic difficulties or might reflect the individual’s efforts to cope with the stresses resulting from the academic difficulties.

The medical evaluation is necessary to explore the influence of health factors on the individual’s availability and ability to learn. Problems in acquiring academic content can be significantly affected by most visual and hearing deficits. Generally poor health can influence the stamina, motivation, and concentration needed to focus adequately on academic performance. In such cases, they may have an impact on learning or be so disruptive as to require removal from a general education setting. However, equally possible is that the frustration and failures caused by a learning disorder or motor skills disorder can be manifested by a disruptive behavior disorder. In some cases, the disruptive behavior disorder coexists with learning or motor skills disorder and the relationship is less clear. Children with ADHD have particular difficulty maintaining attention, and possibly with processing information. As a result, the same variables that have an impact on their attention might also have an impact on their ability to learn. In such instances, they may have a learning disorder and ADHD.

In such instances, they may have a learning disorder and ADHD.
Family Evaluation

A family evaluation must include an assessment of the parents and of the entire family. A judgment is made on the order in which these assessments are best done. The first clinical question is whether the family is functional or dysfunctional. If the family is largely functional, there may be “normal” parenting issues that may be contributing to the child’s difficulties. If there is no evidence of a psychopathological process within the family, alternative explanations should be considered for the learning disorder.

Normal parenting issues may include the time or energy that parents have in relating to the child’s academic difficulties. For example, a single parent may be overwhelmed with responsibilities associated with child-rearing and, as a result, be unavailable to facilitate the child’s educational progress. In families in which both parents work, the demands associated with work may leave little energy for helping the child with academic challenges. There could be family values that affect the child’s educational functioning. The psychiatrist may also learn that education is not a family priority and that this may be in conflict with the demands and the expectations of the school.

If the family is found to be dysfunctional, the psychiatrist must assess whether the dysfunction is caused by issues involving both parents, problems with one parent,
or broader family difficulties. If there is stress between the parents that results in marital difficulties, the psychiatrist should clarify whether these problems are primary or secondary to the presenting academic problems. That is, the marital stress may be contributing to the child’s academic difficulties or may be influenced by the stress of having a child who has a learning disorder. The assessment may clarify that one parent is having psychological problems that are contributing to the couple’s or family’s stress. If there is family dysfunction, the psychiatrist must clarify, when possible, the difficulties that are having an impact on the family. It should be clarified whether the family dysfunction is primary or secondary to the child’s academic difficulties.

**Environmental and Cultural Assessment**

Learning problems are attributed to cognitive deficits or behavior problems in the child or adolescent. Environmental factors involving the school or community, however, can also contribute to academic difficulties. Thus, the psychiatrist should be aware of how social, cultural, and institutional structures can influence learning. In many instances, such an awareness is developed over time and in the process of conducting a clinical practice. Data collection within this context is accomplished through formal and informal observations of the system and the cultural milieu. Through ongoing interactions with the community and the school system, a psychiatrist may develop an appreciation of the community values and the general programmatic resources provided by the school. With this understanding as a backdrop, one can conduct a more direct assessment of how specific environmental or school considerations can affect a given individual.

A child or adolescent with specific needs may be further impaired because of a limited range of services offered by the school system. For example, a child’s learning disorder may require special accommodations and services within a specific classroom; however, the school may not have allocated sufficient resources to make these accommodation or services available. In addition, the effectiveness of school programs can be influenced by interpersonal considerations, such as the competence and personality of the teacher or school administrator. School personnel may be misinformed or uninformed about a particular psychiatric condition or have insufficient training to effectively address a particular learning difficulty. Although uncommon, more troubling influences on a child’s learning may emerge when the school personnel exhibit biases or personality difficulties that affect the teacher’s ability to teach. In addition to problems associated with school personnel, the degree to which the child’s peers value academic success can either motivate or discourage a student from reaching his or her academic potential. An assessment of school-based interpersonal conflicts and alliances can provide valuable insights into their influence on learning. Whereas the school exerts a more direct influence on learning, the community influence is less direct, although no less profound. For example, the value system of some communities includes high expectations for academic accomplishments, whereas other communities view academic success as largely unobtainable. Similarly, inappropriate peer pressure can either minimize or degrade the importance of academics. In most affluent communities, unusually high academic standards can place pressure on a student who has average intellectual capabilities.

**Epidemiology**

The true prevalence of these disorders is not known. The difficulty is that many case definitions are used in different studies. Even if the discrepancy model is used, the amount of discrepancy required may vary. The Centers for Disease Control and Prevention (1987) attempted to establish the prevalence of learning disabilities. These researchers concluded that because the definition and the diagnostic criteria have not been fully standardized, consistency in the design of prevalence studies has not been maintained. Thus, accurate analyses of data over time are not possible. In the absence of good prevalence data, these researchers concluded that between 5 and 10% was a reasonable estimate of the percentage of persons affected by learning disabilities.

In DSM-IV-TR, prevalence figures are noted for each of the learning disorders and motor skills disorders. The prevalence of reading disorder in the United States is estimated at 4% of school-age children. It is estimated that 1% of school-age children have a mathematics disorder. No data are noted for disorder of written expression. The prevalence of developmental coordination disorder is estimated to be as high as 6% for children in the age range of 5–11 years.

**Comorbidity Patterns**

Comorbidity studies suggest that there is a continuum of neurologically based disorders often found together. The common theme appears to be that something impacted on the developing brain very early in pregnancy, causing areas of the brain to develop differently. For some of these individuals, there is a familial pattern, suggesting a genetic theme. For others, the reasons are not clear. There is increasing concern with the impact of environmental toxins found in the air, water, and food that act as developmental and neurologic toxins and impact on brain development.

This continuum may include cortical-based disorders (learning, language, or motor disabilities or organization/executive function disabilities). Individuals with these cortical-based disorders may also have ADHD or a pattern of emotional regulatory problems, including anxiety disorders, depression, anger control difficulties, or obsessive–compulsive disorder.

Many also have tic disorders. Recently, bipolar disorder has been added to this list (see Table 43–3).

Statistical studies supporting the concept of a continuum of neurologically disorders include the following. For individuals with learning disabilities, 20–25% have ADHD (Halperin et al. 1984, Silver 1981). Between 70 and 80% of individuals with ADHD have a learning disability (Silver 1981). About 60% of patients with Tourette’s disorder have a learning disability (Hagin et al. 1982, Hagin and Kugler 1988). Further, 50% of individuals with Tourette’s disorder have ADHD (Comings 1990, Comings and Comings 1988). Fifty percent of patients with Tourette’s disorder have obsessive–compulsive disorder (Frankel et al. 1986, Pauls et al. 1990).

The Cortical Disorders
The learning and motor cortical-based disorders are discussed in this chapter. The language disorders are discussed in Chapter 44.

Attention-Deficit/Hyperactivity Disorder
Attention-deficit/hyperactivity disorder is discussed in Chapter 44.

Regulatory Disorders
Several areas of the brain are needed to regulate emotions and thoughts. If these systems are not working efficiently, the individual might experience difficulty regulating anxiety, mood, anger, or thoughts and actions. The clinical outcome might be an anxiety disorder, depression, intermittent explosive disorder, or obsessive–compulsive disorder. Characteristic of these disorders is that the behaviors have been chronic and pervasive in history and that there is often a familial history of similar problems.

It is true that individuals who struggle in school or who are hyperactive, inattentive, and impulsive might be anxious, depressed, or have difficulty with anger. However, if these behaviors are secondary to the frustration and failure associated with the learning disorders, the clinical history shows that the behaviors started at a certain time (perhaps starting school after a summer break) and only occur during certain times (in class, homework time).

Comorbidity studies suggest that this pattern of disorders is frequently found together. Thus, if the individual has any one of the disorders noted, there is a higher than would be expected possibility that he or she will also have one or more of the other disorders. Thus, it is likely that a child or adolescent with a learning disability will also have ADHD; he or she may also have an anxiety disorder and/or clinical depression and/or an anger-control problem, and/or obsessive–compulsive disorder. Equally true, he or she might have a tic disorder or bipolar disorder. An excellent review of these patterns of comorbidity can be found in Brown (2000).

What About the Disruptive Behavioral Disorders?
It is not uncommon for children and adolescents with learning disorders or a motor skills disorder to have psychiatric disorders other than those discussed above. These are the Disruptive Behavioral Disorders, Oppositional Defiant Disorder (discussed in Chapter 44) and Conduct Disorder (discussed in Chapter 44).

Both of these disorders are reflective of the coping mechanisms children and adolescents might use to handle stress. All too often, the unrecognized and unaddressed stresses relate to lack of school and social success resulting from learning disabilities and/or motor disabilities.

Studies of youths diagnosed as having a conduct disorder or young adults diagnosed as having a personality disorder, especially the borderline type, show that about one-third have unrecognized or recognized and poorly treated learning disabilities (Forness 1981, Hunt and Cohen 1984). Similar findings have been observed with adolescent boys in detention centers (Berman and Siegal 1976, Keilitz et al. 1979, Lewis et al. 1979, Mauser 1974, Robbins et al. 1983).

Treatment approaches must be designed to address both the emotional and behavioral problems and the underlying causes for the life stresses, the learning disabilities, or motor skills disorder. Efforts to treat the presenting emotional or psychological difficulties without efforts to treat the underlying academic problems do not usually succeed.

Social Problems
The learning disabilities that result in learning disorders or motor skills disorder may directly contribute to peer problems by interfering with success in doing activities required to interact with certain age groups. Examples are visual perception and visual–motor problems that interfere with the ability to quickly do such eye–hand skills as catching, hitting, or throwing a ball and fine motor problems that interfere with the ability to tie shoes or properly control eating utensils.

Successful peer interactions are essential to social success. If the learning disabilities or motor skills disorder prevents the individual from being successful in a sport or to do the required tasks for a club or activity, he or she will have social problems. Individuals with a language disability may have a problem with small talk or with quickly processing and responding to conversations (Silver 2006).

Recent research has clarified what are now called pragmatic social skill difficulties. These children have what is believed to be a neurological basis that involves a dysfunction in the brain’s right hemisphere. These children have difficulty understanding the subtle visual or auditory cues that are essential in nonverbal communication (Hazel and Schumaker 1988, Rourke 1987, 1988, Rourke and Fuerst 1991). They lack the ability to read social cues that most know intuitively.

These nonverbal communications that are so essential for social interactions might include visual or auditory inputs.

Visual Perceptions

• Facial expressions: Facial movements and poses communicate emotion. Effective eye contact and the appropriate interpretation of facial expressions (happy, anger, frustration . . . ) are essential.

• Postures and gestures: Postures refers to the positions of the entire body that convey messages that might conflict with spoken words, confusing communication efforts. Gestures involve parts of the body, such as hand and arm movements that communicate meaning.

• Interpersonal space and touch: People have a personal comfort space around them. If a child stands too close to others while talking, that child is violating the rules of personal space. A child who touches others
inappropriately, either in terms of the location or the intensity of the contact (e.g., hugging), breaks one of the unwritten laws of touch and might cause anger or rejection. There are cultural differences that determine how comfortable each person is with space and touch.

Auditory Perception

- Paralanguage: Those aspects of sound that communicate emotion and are used either independently or with words; for example, whistling or humming or the tone, intensity, and loudness of voice.
- Rhythm and time: Rhythm includes speech patterns, attitudes, and speed of movement or speech. Time refers to the speed of speech. Problems arise when the child is out of sync with others.

Children and adolescents with pragmatic social skill problems have difficulty correctly reading the other individual. They often have equal difficulty understanding how others might read their nonverbal cues. The facial expression and body stance suggest that the child is angry. The other person asks, “Why are you angry?” The child responds, “I’m not angry.”

Children and adolescents with these pragmatic social skill problems have difficulty with relationships. Without knowing why, they seem to annoy peers and adults. Without understanding, they do not understand what they are doing and have little idea how to change. For most, pointing out what they do is not successful. They need to be taught these pragmatic skills and then shown how to use them.

Differences in Developmental, Gender, and Cultural Presentations

Earlier studies often noted an increased prevalence of learning disabilities in boys. The ratio ranged from 3:1 to 5:1 and higher (Ackerman et al. 1983, Rutter et al. 1970, 1976). Some studies suggested that this increased prevalence in boys may, in part, be explained by referral bias. Because they are more likely to exhibit more physical aggression and loss of control, boys are more likely to be referred for study (Berry et al. 1985). Girls tend to be more verbal and display less physical aggression. Girls with learning disabilities tend to have more cognitive, language, and social problems and to have significant academic difficulties (Lyon 1997, Shaywitz et al. 1995, Vogel 1990). In the Shaywitz studies (Shaywitz et al. 1990), all children in a specific grade were evaluated for a possible learning disability. These data were compared to the students who had been identified by their school system as having a learning disability. The school-identified population showed a 3:1 ratio of boys to girls. The Shaywitz data, based on assessing all children, showed a ration of 1:1. Johnson and Blalock (1987) also found no specific cognitive differences or patterns of problems between the sexes.

Etiology

Cognitive and Language Studies

The specific constructs for understanding the probable cognitive and language bases for the specific learning disorders and motor skills disorder are discussed under each subtype in the section on treatment. The premise is that there are neurologically based processing problems that result in the disabilities.

Neurological Studies

Earlier research focused on the concept of brain damage (Knobloch and Pasamanick 1959, Towbin 1971). Subtle central nervous system damage may result from circulatory, toxic, metabolic, or other forms of insult to the fetal nervous system during a critical period of prenatal development, perinatal stress to the brain, or stress to the nervous system during a critical period of prenatal development, prenatal stresses to the brain, or stress to the nervous system during the critical early ears of life (e.g., trauma, fever, inflammation). There may be a spectrum of disorders caused by prenatal, perinatal, and postnatal brain damage. Depending on location, extent of damage, time of life, and developmental stage at the time of damage, the stress might cause fetal or neonatal death, cerebral palsy, epilepsy, or mental retardation. The less severe forms might produce a variety of learning disorders.

More of the later research focused on physiological changes rather than on structural changes, that is, on the types of impacts that might affect the developing nervous system, causing areas of the brain to “wire itself” differently than expected. Galaburda et al. (1985), doing microscopic studies of brains of individuals known to have learning disabilities, showed a consistent pattern of cortical cells that maintained an earlier developmental stage of migration and development, suggesting that something had an impact on the brain during development, halting or slowing down the normal developmental stages. Some of the factors studied as possibly contributing to the stress that results in neurological dysfunction are maternal cigarette smoking during pregnancy, use of alcohol or drugs during pregnancy, convulsions during pregnancy, low fetal heart rate during the second stage of labor, lower placental weight, breech presentations, and chorionitis.

Research has also focused on the genetic basis for these disorders. Several studies have shown a familial pattern in approximately 40–50% of children with learning disabilities (Cantwell 1975, Morrison and Stewart 1971, Silver 1971). In longitudinal studies of twins, identical pairs are more likely than fraternal pairs to be concordant for academic difficulties (McCarty and McCarty 1969). Recent findings suggest a possible connection between environmental toxins and the increased incidence of developmental, learning, and behavioral problems (PSR 2000). The National Academy of Science released two studies (NAS 2000a, 2000b) on general developmental and specific neurologic toxins. U.S. companies reported to the Environmental Protection Agency that in 1998 they released a total of 1.2 billion pounds of chemicals into the nation’s air and water that have the potential to affect the way a child’s body and brain develop. More than half (53%) of these are known or suspected to be developmental or neurologic toxins. There is great concern about the impact of these environmental toxins on the increased incidence of developmental, learning, and behavioral problems.

Research in reading disorders shows an inability to segment the written word into the underlying phonologic components (Shaywitz 1996, Talial 1985). This deficit in
phonological awareness impairs decoding, preventing word identification. This basic deficit in what is essentially a lower-order linguistic function blocks access to higher order linguistic processes and impairs the child’s ability to gain meaning from text. Thus, the child has difficulty with reading fluency and with text comprehension. It is not uncommon to find a spelling disability associated with a reading disorder because spelling requires the same phonologic skills as reading.

Studies of the brain using functional magnetic resonance imaging clearly shows a difference in brain function between individuals who have no reading problems and those with a reading disorder (Shaywitz et al. 1998). Brain activation patterns differ significantly between groups of individuals with a reading disability and those without, showing relative underactivation in posterior regions (Wernicke’s area, the angular gyrus, and striate cortex) and related overactivation in an anterior region (inferior frontal gyrus). These results are seen as confirming that the impairment in reading disorders is phonologic in nature and these brain activation patterns may provide neural proof for this impairment.

Research in disorders of written expression focus on the need for immediate and automatic carrying out of most of the lower level mental activities required for skilled writing. These lower level mental activities guide handwriting, spelling, word choice, and the construction of sentences that conform to the conventions of written language. Lower-level mental activities also guide the construction of textural connections, specifically, spacing and punctuation. The writer’s attention can then focus on the content, organization, and clarity of the task. One can shift attention between levels of mental processing without losing control of the flow of the text. Difficulties with lower-level mental activities appear to be the source of the problem in expressive writing disorders (Torgeson 1982).

Research on mathematics achievement suggests that there may be four primary factors involved: language, conceptual, visual–spatial, and memory (Bryan and Pearl 1979). In addition, knowing how to use the correct strategies is important (NAS 2000a). Proficiency in mathematics requires more than computational skills. The difficulty might be in an inability to develop a systematic plan for problems solving. Memory is also essential to the ability to do mathematics. One must retain basic number facts. In addition, it is necessary to remember specific equations or other steps necessary to solve a problem. Once a problem is started, students must remember where they are in the process as they proceed from step to step.

**Treatment**

Treatment is directed at the underlying disabilities by use of educational interventions. Psychological interventions are also directed at any existing emotional, social, or family difficulties.

**Educational Interventions**

The goal of general and special education interventions is to help children and adolescents overcome or compensate for their learning disorders or motor skills disorder so that they can succeed in school.

These efforts involve remedial and compensatory interventions and use a multisensory approach that facilitates building on all areas of strength while compensating for any areas of weakness. These efforts are to be provided in as close to a general education classroom setting as possible. It is essential that the classroom teacher knows how to adapt the classroom, curriculum, and teaching style to best accommodate each student’s areas of difficulty.

**Educational Interventions for Reading Disorders**

Longitudinal research indicates that children with reading disabilities who struggle with the early stages of reading, particularly the development of phonological awareness and decoding, are faced each year with increasing obstacles to literacy development (Adams and Bruck 1995, Torgeson and Burgess 1994). Because they cannot pronounce words and read fluently, they struggle to comprehend and gain conceptual knowledge (Beck and Juel 1995, Shaywitz et al. 1995). Reading problems become a threat to children’s entire education and future (Hall and Moats 1999, Juel 1988). Approximately 40% of students with learning disabilities drop out of school (Lichtenstein and Blackorby 1995, Malian and Love 1998).

The process of reading involves two tasks, decoding or word recognition and reading comprehension. Only after these two steps can someone store and retain the information (reading fluency). Decoding refers to the act of transcribing a printed word into speech. Comprehension refers to the process of interpreting the message or meaning of the text. Decoding is unique to reading and is different from the recognition of words in speech; however, the linguistic skills that subserve reading comprehension are the same for both reading and listening (Gough and Tunmer 1986).

Most students with a reading disorder have difficulty acquiring the knowledge and skills essential for rapid automatic decoding. Reading comprehension, thus, is limited by weak decoding skills. Because spelling uses the same knowledge as word recognition, it is also frequently impaired.

Direct instruction in reading is considered the essential treatment for a student with a reading disorder. These efforts are provided by a person trained to use appropriate remedial methods. These methods emphasize explicit instruction in letter–sound associations. This instruction is described as a multisensory approach. For example, children see a letter and hear its name and sound; they trace the letter, saying its name and sound; and then they write the letter, repeating its name and sound.

Sounds and letters are blended to form words. Reading, spelling, and writing are often taught simultaneously. Instruction involves extended practice and is supplemented by speech segmentation training and study skills instructions. Parents are asked to read to the children to enhance appreciation of reading and to give the children access to knowledge normally obtained by reading.

Once reading decoding becomes automatic, the focus shifts to reading comprehension and to retaining the information obtained from the reading. Each step must be addressed and techniques provided to help the student master each step.

Reading disorders are not “cured.” With appropriate interventions, children and adolescents with reading disorders learn to read and spell at a slower rate than normally developing individuals do. It is essential for these students to learn compensatory skills and for the classroom teacher to provide essential accommodations.
Educational Interventions for Mathematics Disorders

Children and adolescents with a mathematics disorder may have a wide range of symptoms, including delays in the acquisition of basic spatial and number concepts, problems learning and using number words and number facts or writing numbers correctly and in correct alignment when doing computations and difficulty in applying arithmetic skills when solving everyday problems (Flieschner and Garnett 1993, Kose 1992). Because mathematics achievement is highly dependent on the quality of instruction offered students, it may be that a significant number of those students who are found to have a mathematics disorder in fact do not have an intrinsic mathematics disorder, but rather have not had appropriate instruction (Carnine 1991).

The understanding of the reasons for difficulty mastering mathematics is less advanced than the understanding for reading disorders. Studies clarify predictable stages through which children progress when they are learning to do arithmetic calculations (Ginsburg 1992). Initially, the child learns informal knowledge about numbers, based on experience and strategies that develop without instruction. Relying on this informal knowledge, children devise counting procedures for solving quantitative problems. Problems often arise when children are introduced to the formal knowledge about mathematics that is presented in school. This formal knowledge depends on understanding and the correct application of complex algorithms that are not intuitively clear to the child. Problems may arise when children are asked early in their school years to memorize number facts. Children with delays in the development of information-processing strategies that are fundamental to memory may soon fall behind.

Treatment for a mathematics disorder involves general concerns and specific interventions. Initially, the problem of anxiety, withdrawal, defeatism, or other responses to repeated failure must be addressed (Torgeson 1982). Much of the teaching of mathematics is based on criticism of failure. The emphasis is on getting the right answer rather than on problems solving. Because of this overfocus on getting the right answer, children may have performance anxiety or feel that they are stupid in mathematics. For some, the premature pressure for speeded answers can short-circuit understanding, capitalization, or composition. Both reading and writing require the ability to attach the correct sounds (phonemes) to the correct symbols (graphemes). Reading requires the ability to decode letters into sounds and to blend these sounds into words. Writing requires outflow of the language or sounds in the brain back into graphic symbols. Thus, reading and writing problems are frequently seen together.

It is helpful to distinguish between a fine motor problem that results in difficulty with the mechanics of writing, a graphomotor problem, and a language-based learning disability that results in problems with the language of writing. Individuals with a disorder of written expression might have a fine motor problem but always have a language-based disorder, resulting in difficulty with spelling, grammar, punctuation, capitalization, or composition.

Poor spelling might be the first indicator of a writing disorder. By third or fourth grade, additional writing problems are apparent. Children with a writing disorder exhibit grammatical and punctuation errors at the sentence level. Paragraphs are poorly organized. In later grades, the ability to get thoughts onto the page in an organized way may be seen. In later grades, the speed of processing information may result in difficulty taking notes.

Treatment for a writing disorder might involve a skills approach or a holistic approach. Skills programs are often used with younger children and focus on letter–sound associations, with emphasis on reading and spelling (Cox 1984, Slingerland 1971). Children may be asked to listen carefully for the sounds in words and then to represent these sounds with written letters, saying each letter aloud as it is written.

The holistic approach to writing begins with the student’s ideas. It involves a series of highly structured steps for narrowing ideas to one topic, writing a first draft, reading it aloud to an audience of peers, and then refining organization and language. The final step involves working on mechanics in preparing for “publishing” a draft for peers to read.

The conceptual underpinnings of the subject; some have problems related to procedural learning, recall of discrete information, and self-monitoring. Remedial efforts must take into account the student’s areas of learning abilities and learning disabilities.
Educational Interventions for Developmental Coordination Disorders
The approaches for helping children and adolescents with this disorder focus on academic skills, life skills, and athletic skills. That is, the focus of intervention might be on specific skills needed for school (e.g., handwriting), on dressing and other life skills (e.g., buttoning, zipping, tying, eating), or on skills needed to do better in sports (e.g., catching, hitting, throwing, running).

Occupational therapists work in all of these areas using sensory integrative approaches involving visual, visual–motor, gross motor, fine motor, proprioceptive, and vestibular stimulation and, when possible, strengthening to improve functioning. Within school systems, the special education professional may work on handwriting and the adaptive physical education teacher may work on sports-related activities.

Psychotherapeutic Interventions
Learning disorders affect all aspects of the child’s or adolescent’s life. The same processing problems that interfere with reading, writing, mathematics, language, and motor skills may interfere with communicating with peers and family, with success in sports and activities, and with such daily life skills as dressing oneself or cutting food (Silver 2006).

Lack of success in school can lead to a poor self-image and low self-esteem (Black 1974, Bryan and Pearl 1979, Rogers and Saklofske 1985, Shaw and Levine 1982). These individuals might feel that they have minimal control over their life and compensate by trying to be in more control. Some individuals may become anxious or depressed, or may develop a disruptive behavior disorder.

Genetic and family studies show that in about 40% of children and adolescents with learning disorders, there is a familial pattern (discussed earlier). Thus, from an early identification perspective, each sibling must be considered as possibly having a learning disorder. Also, there is a 40% likelihood that one of the parents may also have a learning disorder. This parent may not have known of this problem. If this is true, for the first time the parent may be able to understand a lifetime of difficulties or underachievement. Further, when the psychiatrist offers suggestions for the parent, the parent’s areas of difficulty must be considered. The psychiatrist should not ask a mother to be more organized when she has been just as disorganized as her child all her life.

Some children or adolescents may need specific individual, behavioral, group, or family therapy. If so, it is critical that the therapist understand the impact that the learning disorder has had on the individual and how these disabilities might affect the process of therapy. Students with social skills difficulty, especially those with pragmatic social skill disorders will benefit from group social skills training.

Education of the Individual and Family
Once the diagnosis is established, it is critical for the psychiatrist to explain to the individual and to the parents what the problems are, focusing not only on the areas of difficulty but also on the areas of strengths. The data from formal testing is important in knowing what to review with parents. If the report is too technical, the psychiatrist should discuss the findings with the person who did the test so that it is possible to explain the results to others.

Parents must understand this information so that they can develop a better understanding of their child or adolescent (Silver 2006). Mental health professionals working with these individuals must understand the concept of learning disabilities (learning disorders) and motor skills disorders well enough to teach the individual and family members what the areas of disabilities and abilities are, as well as the effects these disabilities have had on peer, family, and school activities.

The child or adolescent needs to begin to understand and to rethink concepts of self. Parents will have to modify their images of their son or daughter and modify their responses and behaviors. Siblings may gain a new understanding of the family problems.

If the presenting behavior problems are not serious, it may be best first to provide family education and to give some time to see how this knowledge affects the family. Concurrently, the parents are taught how to advocate for the necessary services within the school system. It may be that once the academic issues are addressed and the family begins to change, the behavior problems will diminish and no further help will be needed.

If needed, the next step is family counseling. Parents are taught how to use their knowledge of their son’s or daughter’s strengths and weaknesses to modify family patterns; select appropriate chores, choose appropriate activities, sports, and camps; and address stresses within the family (Silver 2006). Once they are taught the necessary knowledge about their child or adolescent and the concepts of intervention, families can often move ahead, creatively working out their own problems.

Individual Therapy
For some children and adolescents, individual behavioral therapy or psychotherapy may be indicated to help them develop new strategies for interacting with peers, teachers, and parents. The models for this therapy are the same as for any other therapeutic approach. However, knowledge of these disorders and school history help both the therapist and the individual with the learning disorder better understand how certain problems or patterns of behaviors evolved. Because this form of therapy requires listening and talking, it is important for the therapist to know whether the individual has a language disability that might impact on their ability to communicate. If so, the therapist has to develop ways of accommodating these problems if therapy is to progress. If a speech and language therapist is working with the individual, she or he might offer suggestions.

Family Therapy
The initial phases of family therapy might focus on helping the identified patient regain control over his or her behavior and helping the parents retake control of the family. A behavioral management approach is often the first intervention.

The model of family therapy used will depend on the needs of the family and the orientation of the therapist. It is important for the therapist to keep in mind the impact the disabilities has on the individual and the family. It is also important to keep in mind the impact these disabilities might have on this individual’s ability to participate in the
family therapy. As with individual therapy, if the individual has difficulties with oral communication, he or she might have difficulty participating in the sessions. Accommodations will be needed.

Social Skills Training

Children and adolescents with learning and/or motor disorders often have problems with peer relationships (Hazel and Schumaker 1998, Rourke 1988). There appears to be an association between poor peer relationships and a high risk for later psychological problems as well as dissatisfaction and loneliness (Asher and Wheeler 1985). Poor childhood social skills and peer acceptance have been related to adjustment problems in adulthood (Gresham and Elliott 1989, Wiener et al. 1990). Thus, it is important to address these problems early.

As noted earlier in this chapter, the social skills difficulties might be secondary to the learning and/or motor problems. Alternatively, they might be another reflection of a dysfunctional nervous system, pragmatic social skills problems. In both situations, social skills training is helpful.

Such interventions attempt to enhance social–cognitive skills and are directed at altering specific behavior patterns (Dodge 1989, McIntosh et al. 1991). Social–cognitive approaches are based on those cognitive processes that are related to competent, prosocial behavior. Targets of intervention are directed toward the underlying cognitive variables that are linked to positive peer acceptance.

In general, the enhancement of social–cognitive skills typically involves three kinds of skill development: (1) accurate interpretation of social situations; (2) effective use of social behaviors in interactions with others; and (3) the evaluation of one’s own performance and the ability to make adjustments, depending on the environmental context. The first step typically requires the clinician to provide direct instructions concerning the relevant skills (e.g., reading body language, conversational skills). The skills taught are then modeled by the clinician, stressing the positive outcomes associated with these skills. In the process, the clinician will confront and restructure thoughts that may inhibit the desired behaviors. The child is then required to rehearse the skills within the group with the clinician providing reinforcement and corrective feedback. Generalization is stressed through homework assignments whereby skills are attempted in the natural environment and classroom (Dodge 1989, McIntosh et al. 1991).

Use of Medications

No medication has been found to be effective for treating learning disorders or motor skills disorders. If the individual also has ADHD, it is important that medication be used to minimize the hyperactivity, inattention, and/or impulsivity so that the student can be available for learning.

Summary

Research on the etiology as well as on the brain dysfunction involved with learning disorders and motor skills disorders have resulted in a better understanding of these neurologically based disorders. Scientifically based interventions now lead to better results within the educational setting. It is critical for the clinician working with these children and adolescents to understand the impact these disabilities have on school, peer, and family life. To label the resulting behaviors and design a treatment plan based on these behaviors will not be successful. The disabilities and the impact of the disabilities must be addressed if any success is to be achieved.

Educational and academic success is critical to psychosocial growth and development as well as to the individual’s role within the family, with peers, and when participating in activities or sports. It is critical for the clinician to recognize clinical evidence of these disorders and to make the proper referral to clarify the disorders. It is equally essential to collaborate with the educational and other professionals working with the child or adolescent.

### Clinical Vignette 1

Billy started first grade and did not do well. He did not master the early skills of reading and writing. The school decided to have him repeat first grade. He struggled through this year but fell further and further behind. When he entered third grade, he was overwhelmed. He knew that he was a year older than the other students. He was unable to do the work in class or at home and he felt frustrated and stupid. Soon, he began to clown around in class and to get into fights with the other students.

Two other things happened during this third-grade year. First, his teacher became frustrated. She was trying to help him learn and he was not making progress. He was disrupting the class and preventing her from teaching the other children. The teacher handled her frustration by blaming the parents. She called them, “Billy is not completing his schoolwork.” “His homework is incorrect.” “He is teasing and fighting with the other children.” She seemed to be saying to the parents, “Do something. Fix your kid.” She did not realize that the parents were just as confused and frustrated as the teacher. Second, the parents began to disagree on parenting decisions. One felt that the best way to help Billy was to be firm and strict and the other felt that the best way was to be understanding and permissive. They began to argue with each other and became less available to support each other.

Finally, the principal asked the parents to come to school. They were informed that Billy was not making academic progress. They were also told that the reason for his failure was that he was emotionally disturbed because of the apparent marital conflicts. The parents were encouraged to see a mental health professional. The psychiatrist found clinical evidence suggesting that Billy had difficulty with reading, reading comprehension, handwriting, and written language. He found Billy to be frustrated with a poor self-image and low self-esteem. The parents seemed to be competent people who were also frustrated with Billy’s difficulties. A full psychoeducational evaluation was requested. The results showed Billy to be of above-average ability but to have significant learning disabilities.

The psychiatrist concluded that the primary diagnosis was the learning disability. The emotional, behavioral, social, and family problems were secondary to the frustrations and failures experienced by Billy, his parents, and his teacher. By working with the family, he helped to get Billy identified as having a disability and to obtain the necessary services to help him succeed. His behavioral problems diminished and then ceased.
Danny was referred at age 7 years because his teacher and his parents thought he was depressed. The following is part of the process notes of the first session. The child’s comments are noted; the psychiatrist’s comments are in parenthesis.

(Tell me about school.) I don’t like to make mistakes. (Oh.) I get angry and frustrated. (What do you do?) Sometimes I feel like crying but I tough it out. (You can’t cry?) The kids would think I was a baby. (What else do you feel?) I get angry with myself. I say I’m dumb or stupid or can’t learn. (How do you feel when you say these things?) Bad. I’m just a jerk. (What do you do with these feelings?) I distract myself until they go away.

(Danny, why do you think you feel this way?) I don’t know. (Could it have something to do with school?) I don’t read or do math good. (And the other kids . . .?) They do it easier. (When you say that, you look upset.) Yea.

(What else happens in school?) I get scared sometimes that the teacher will be angry with me. (I see.) If she doesn’t like my work she sends me back to do it again. I get mad because I did my best. (What do you do?) I distract myself and push it out of my mind. Then I do the work. (How do you push away such angry feelings?) I get busy with the work. (Don’t you feel like yelling or throwing something, or . . .?) No, that would be bad.

(You know, Danny, I get the feeling that you don’t like yourself too much.) There’s nothing to like. (You mean you cannot think of anything about yourself that is good?) I guess I’m alive. (As I listen to you I begin to feel very sad. I wonder if you feel the same way.) Yea.

(How do your Mommy and Daddy feel?) They love me. (Oh?) I’m their child. (And that’s the reason.) I guess. (You guess?) Well, sometimes I think that Mommy wanted a girl because they don’t cause as much trouble as boys. But, they may want a boy to carry on the family name. (So, you may not like yourself and now I hear you say that maybe your parents don’t like you either.) Sometimes I think that.

You know, Danny, I think the real problem is that you don’t like yourself. Yea. (And, you look so sad right now.) How long have you had such feelings and thoughts? I think they started in first grade. I couldn’t do some of the work. The teacher used to make me do it again. The other kids got smiles from the teacher. I just got disappointed looks.

(What do you think was the problem in first grade?) I don’t know. (You seemed to have trouble doing the school work.) Yea. (You know, I’ve worked with other boys and girls with problems like yours. Sometimes they worry that their problems are because they are bad and being punished or because there’s something wrong with their head or maybe because they’re stupid or retarded. I wonder what kind of thoughts you have.) I do think about these things. Maybe. Sometimes I think that maybe I’m retarded. (Retarded?) Yes. (That would be pretty upsetting to think that you were retarded.) Yea. (Maybe we had better find out what the problems are so that you won’t have to worry about things that may not be true.) I’m just too dumb to learn anything. (I can see why you might think that way. Only, I bet you can learn. Only, maybe something is getting in the way. I’d like to find out what it is so that we can do something about it.) I can’t do anything right.

Last year at the pool I hit my head a couple of times. (And, maybe that caused the problems?) Maybe that’s why I’m so dumb. (I don’t think that is the reason you are having trouble in school. But then, I guess it’s hard for you to believe me.) There’s no hope for me.

After this session, sessions with the parents, and conversations with Danny’s teacher, a full psychoeducational evaluation was done. He was found to be bright but to have significant learning disabilities. He was depressed with a poor self-image and low self-esteem. However, these clinical problems were secondary to the unrecognized and untreated learning disabilities.

**Special Considerations in the Doctor–Patient Relationship**

School is the life work of the child and adolescent. Thus, it is essential that psychiatrists be aware of learning and motor skills disorders. It is critical to differentiate between the child whose emotional, social, or family problems result in secondary academic and school problems and the child whose learning, language, or motor problems result in secondary emotional, social, or family problems. The interventions are very different for each.

Once a learning or motor skills disorder is identified, the psychiatrist must understand education law and policy in order to assist parents in getting the best placement and the fullest services for the child. If medication is needed in school, the psychiatrist must know the proper school procedures for directing how this is done.

If a child or adolescent with learning, language, or motor disabilities is seen in psychotherapy, group therapy, family therapy, or any other form of psychological intervention, it will be essential that the psychiatrist understand how these disabilities might present themselves in the session and how to accommodate to them.

**Comparison of DSM IV/ICD-10 Diagnostic Criteria**

In ICD-10, the DSM-IV-TR reading disorder is referred to as “Specific Reading Disorder” and the DSM-IV-TR Mathematics Disorder as “Specific Disorder of Arithmetic Skills.” For both of these learning skills disorders, the ICD-10 Diagnostic Criteria for Research suggest that the cutoff be two standard deviations below the expected level of reading achievement and mathematics achievement respectively. In contrast, DSM-IV-TR does not specify a score cutoff, instead recommending that the score be “substantially below that expected given the person’s chronological age, measured intelligence, and age-appropriate education.” Furthermore, in contrast to DSM-IV-TR which permits both to be diagnosed if present, ICD-10 Specific Reading Disorder takes precedence over Specific Disorder of Arithmetic Skills so that if criteria are met for both, only the reading disorder is diagnosed.

ICD-10 does not include a Disorder of Written Expression (as in DSM-IV-TR). Also, ICD-10 includes a Specific Spelling Disorder. DSM-IV-TR includes spelling problems as part of the definition of Disorder of Written Expression but requires writing problems in addition to spelling in order to warrant this diagnosis.

Finally, DSM-IV-TR Coordination Disorder is referred to in ICD-10 as “Specific Developmental Disorder of motor function.” Furthermore, the ICD-10 Diagnostic Criteria for Research suggest that the cutoff be two standard deviations below the expected level on a standardized test of fine or gross motor coordination.

Introduction

The disorders of communication have traditionally been insufficiently familiar to psychiatrists, despite the fact that psychiatric practice is founded upon communication. A knowledge of these disorders is of especially crucial importance in the care of children, since they are deeply interwoven in all aspects of normal development, psychopathology, and the functions of daily life.

The relationship among language, cognition, and their disturbances continue to stimulate a mass of research and speculation beyond the scope of this chapter (Friel-Patti 1992, Paul 2002). Thus, the classification of these disorders has always been controversial. Prior to the elaboration of DSM-III (American Psychiatric Association 1980) in the late 1970s, they were frequently regarded by psychiatrists as psychopathology manifested by a single symptom, as were elimination disorders, tics, and learning disorders. DSM-III represented an attempt to consolidate the approach of psychiatrists with that of other disciplines. It presented these disorders as specific developmental disorders grouped with academic skill disorders, resulting from the inadequate development of some specific language or speech skill. Deficits due to other demonstrable physical or neurological disorder were regarded as separate conditions. The linkage of language and academic skills or learning disorders, while plausible, has remained controversial, and in DSM-IV-TR (American Psychiatric Association 2000), they are regarded as separate although often associated conditions. This section includes both disorders of speech, the oral representation of language, and disorders of language itself. The disorders included in this section are expressive language disorder (ELD), mixed receptive–expressive language disorders (MRELD), phonological disorder (PD), stuttering, and communication disorder not otherwise specified (CDNOS). These disorders share many common features, as noted in Table 44–1 (common features). Selective mutism is not regarded as a disorder of communication per se, and is included among other disorders of childhood.

Expressive and Mixed Expressive-Receptive Language Disorders

Diagnosis

Definition and Diagnostic Features

ELD denotes an impairment in the development of expressive language. Its diagnosis requires the use of one or more standardized assessment measures that are individually administered. When appropriate instruments are unavailable, as for example, in the case of a member of a population for whom no instrument has been standardized, this diagnosis may be made through a thorough functional investigation of an individual’s language ability. Individuals with this disorder have expressive language scores well below those obtained from measures of nonverbal intelligence and receptive language. DSM-IV-TR does not require any particular degree of discrepancy in scores.

The presence of a test score by itself does not define the condition: the affected individual must have clinical symptoms that might include disturbances of vocabulary, grammar (e.g., tenses), or syntax (e.g., sentence length or complexity). The diagnosis of this condition also requires that the individual having it experiences social, academic, or occupational difficulties directly related to the condition. The presence of an MRELD or a pervasive developmental disorder (PDD) supersedes this diagnosis, and it is not made in their presence. Similarly, it may not be made in the presence of mental retardation, motor or sensory deficits, or
environmental observation, unless the expressive language difficulties experienced are beyond what would be expected for individuals with these conditions. This condition may be acquired, as from a medical condition affecting the central nervous system (CNS), or it may be developmental, in the sense of arising early in life without known origin.

The manifestations of this condition vary with age and severity. Vocabulary, word finding, sentence length, variety of expression, and grammatical complexity may all be reduced. Most children with this disorder demonstrate a slower than expected rate of language development, associated with the developmental subtype. Often auxiliary words or prepositions are omitted, resulting in a telegraphic sort of speech: “He was going to school” becomes “He going school.” Word order of essential importance in English may be garbled: “Him like too me” for “I like him too.” Words or phrases may be repeated to the degree that speech may be echolalic, perseverative, or both. Conversation may be tangential with sudden inappropriate changes of topic, or conversely, perseveration. Pragmatic difficulties, such as in initiating or terminating conversations, and much avoidance of conversation are also frequently seen. Because of these problems, these patients frequently are regarded as socially inappropriate or inept and at times may be suspected of having a formal thought disorder. These children frequently have associated learning problems because of their difficulty in responding verbally to exercises. They may have motor coordination problems and various other neurodevelopmental abnormalities documented upon neurological examination, EEG, or neuroimaging, although no consistent patterns are seen.

The adoption of the category MRELD in DSM-IV-TR represented the most significant change from previous classification systems, which posited the existence of receptive language disorders in a solitary form. The existence of this category reflects the clinical observation that receptive language disorders in children seldom, if ever, can occur without concurrent (and perhaps resultant) problems with expression. DSM-IV-TR notes that this is in direct contrast with such entities as Wernicke’s aphasia in adults, which affects reception alone. Children with these conditions have significant

### DSM-IV-TR Criteria 315.31

#### Mixed Receptive–Expressive Language Disorder

A. The scores obtained from a battery of standardized individually administered measures of both receptive and expressive language development are substantially below those obtained from standardized measures of both nonverbal intellectual capacity. Symptoms include those for expressive language disorder as well as difficulty understanding words, sentences, or specific types of words, such as spatial terms.

B. The difficulties with receptive and expressive language significantly interfere with academic or occupational achievement or with social communication.

C. Criteria are not met for a pervasive developmental disorder.

D. If mental retardation, a speech-motor or sensory deficit, or environmental deprivation is present, the language difficulties are in excess of those usually associated with these problems.

measurable deficits in standardized individual assessments, of both receptive and expressive language, compared to their similarly assessed nonverbal intelligence. These deficiencies may occur in both verbal and sign languages; may interfere with social, academic, and occupational function; and, by definition in DSM-IV-TR, do not occur in the presence of a PDD. This condition may be acquired from some CNS injury or may be purely developmental. In the latter case, affected individuals exhibit a persistent pattern of delayed language development, in which speech develops late and advances slowly. Children with this disorder may manifest any and all of the symptoms of ELD. They also have difficulty with various aspects of receptive language, including misunderstanding of individual words or whole statements and deficits in auditory processing skills (sound discrimination and association, recall, storage, and sequencing).

Children with MRELD may have all the problems of ELD. In addition, they do not understand all that they hear. The deficits may be mild or severe, and at times deceptively subtle, since patients may conceal them or avoid interaction. All areas and levels of language comprehension may be disturbed. Thus, the child may not understand speech that is rapid, certain words or categories of words such as abstract quantities, or types of statements such as conditional clauses. This may cause these children to seem not to hear or attend, or to misbehave by not following commands correctly. At times, when conversation is redirected to them in a slower or more concise fashion, they may understand and respond belatedly if at all. Children with this disorder may manifest any and all of the symptoms of ELD. They also have difficulty with various aspects of receptive language, including misunderstanding of individual words or whole statements and deficits in auditory processing skills (sound discrimination and association, recall, storage, and sequencing).

Assessment

In the Psychiatric Interview

It is essential that the psychiatrist seeing children is familiar with the expected milestones of speech and language development (see in section B of diagnostic decision tree [Figure 44-1]). This knowledge forms the basis for effective observation in a clinical setting. The clinician should ask the parents or guardians about the child’s speech and language, both in terms of development and in terms of current function. Paul (1982, 2002) and Gulley (2005) provide detailed outlines for this, but much can be learned from even a few questions: Does the child seem to hear and understand what is being said? Does the child require visual prompts? Does the child in fact use spoken language to communicate? How long and complicated are his sentences? Does the child “make sense” to outsiders? Can he/she be clearly understood even by strangers? Which sounds does the child find difficult? Does the child use unusual volume, pitch, or nasality? Does he/she observe the rules of conversation? Parent–child communication should also be observed.

Children must be assessed in an environment that fosters verbal communication and observed in a variety of interactions because their speech and language vary so much over time in quantity and quality. For younger children, this may best be done in the context of a play situation. Rutter (1987) recommends that the clinician assesses inner language, comprehension, production, phonation, and pragmatics. “Inner language” means symbolization, which may be observed in a younger child by the child’s representational use of play materials. For example, a block could be a house or a vehicle. “Comprehension” is assessed through conversation and the use of developmentally appropriate questions and commands, especially with nonverbal augments or prompts. The clinician should note how well a child can follow and draw inferences from a conversation. “Production” refers to speech, its fluency, and intelligibility. “Phonation” refers to the utterance of vocal sounds produced by the larynx. “Pragmatics” are those aspects of language that render it useful for social communication beyond the most concrete level. Does the child appreciate the nuances of his/her partner’s conversation, as for example when they signal beginnings and endings of conversations, topical changes, or the patient’s turn to talk?

Pragmatic language involves nonverbal elements. Deficiencies in this area impair abstraction and may render the individual almost “robot like.” In all cases, observations should be made in as relaxed a fashion as possible, avoiding interrogation or rote exercises. If a child fails to communicate a given item, necessary help including nonverbal prompts should be offered, so that the child has the experience of success. A sense of failure will stifle communication.

In the Classroom

In school settings, all of the phenomena seen in a clinical interview may also be pursued. Children with communication disorders often feel challenged by the demands of the classroom and may limit or withdraw from conversation entirely. Thus, the task-oriented group setting of the classroom may not elicit a child’s best communication. It may, however, demonstrate the practical effectiveness of the child’s everyday efforts. At the same time, teachers sometimes have more individual conversations with children than even their parents do, and their experiences may make them the first adults to detect communication problems. In many areas, young children receive some type of formal communication screening in school. Therefore, teacher input is essential in the evaluation of these children.

By the Speech and Language Pathologist

A number of instruments are available for the assessment of communication. Some of these are listed in Table 44-2. Most are beyond the training of physicians whose most important contributions are interview skills and medical assessment, but a familiarity with them can help the physician develop a repertoire and knowledge of screening measures. Because of the complex comorbidity of these disorders, they are often best assessed by an interdisciplinary team (McKirdy 1985, Bagnato and Neisworth 1991, Klykylo
The team’s activities are usually coordinated by a case manager, who often is a pediatrician or a child and adolescent psychiatrist, and who usually has primary clinical responsibility in the case. The audiologist is an essential contributor to this process, since, in the first place, one must rule out a hearing disorder in any communication disorder. Children of any age, even infants, can be assessed audiologically. Psychological assessment is necessary to delineate the child’s cognitive abilities and may also cast light on the child’s emotional state through projective testing. Medical specialists including pediatric neurologists and otorhinolaryngologists, as well as child and adolescent psychiatrists, should be appropriately involved. The educational specialist or liaison special educator has particular competence in developing an education prescription for the child, in assisting the family in the procedural (and at times legal) efforts required to arrange appropriate educational services, and in helping classroom teachers to develop effective pedagogic approaches.

**Epidemiology**

Past reports of prevalence and incidence of communication disorders have been complicated by variations in setting, case finding, and diagnostic criteria. Numbers from 1% to 13% have been posited for the prevalence of language disorders and numbers as high as 32% for speech disorders (Baker 1990, Weindrich et al. 2000). Acquired language disorders are reported to be less common than the developmental types. Overall, between 3% and 7% of all children were suspected of having a developmental ELD. MRELD is less common but may still be seen in as many as 3% of school-age children.
Comorbidity

PD is especially common among children with these disorders. In addition, many of these children may present at least some manifestations of learning disorders. Other conditions that are broadly considered as neurodevelopmental are also noted in these children, such as motor delays, coordination disorders, and enuresis. The extent of these associations, while apparently considerable, is difficult to quantify because of methodologic variations in the literature. The combination of these disorders and the stresses they create frequently lead to adjustment disorders and social withdrawal.

Among children with a psychiatric diagnosis made first, there is a remarkably increased likelihood of speech and language disorders, which often go undetected (Cohen et al. 1993). Typical are the studies of Beitchman (1985) who found more than four times the prevalence of psychiatric illness in kindergartners with communication disorders compared to nondisordered children. Some studies also suggest that psychiatric illness is associated with greater severity of communication problems. For example, in Cantwell and Baker (1991), in a population of 302 children with a psychiatric diagnosis as well as a speech and language disorder, the subjects were more likely to have multiple or more severe language disorders than speech- and language-disordered children who were psychiatrically well. Unfortunately, language disorders too often are unsuspected by parents and professionals alike.

Cantwell and Baker (1991), in their seminal work, found that the most common psychiatric disorder among children with communication disorders overall was attention-deficit/hyperactivity disorder (ADHD), representing 19% of their sample of 600 children referred for a communication evaluation. The combination of language and disruptive behavior disorders appears to be associated with greater severity of impairment in both disorders. Some authors have speculated that ADHD may be concordant with a putative entity known as central auditory processing disorder (CAPD), which refers to deficits in the processing of audible signals and which can be subsumed under the DSM-IV-TR language disorders. A total concordance is unlikely, but Riccio and associates (1994) suggest that 50% of children with CAPD also have ADHD. Ongoing work in neuroimaging and brain activity measurement may be expected to delineate this area more fully.

Course

Contrary to some popular beliefs, language disorders do not always spontaneously resolve, nor do children always “grow out of it.” In general, the course of these disorders is lengthy, and the more severe disorders are usually more persistent. Language disorders of the developmental type are generally recognized gradually as children grow up; the less severe cases are identified later in childhood or adolescence. Language disorders acquired secondary to other medical illnesses tend to occur more precipitously and can appear at any age. In the case of ELD, DSM-IV-TR reports that most children with this condition acquire more or less normal language abilities by late adolescence but that subtle deficits may persist. The prognosis is worse in the case of MRELD, and only a minority of these children are free from some communication problems in adulthood. Even when their communication skills seem grossly normal, subtle deficits may persist, and they may go on to manifest learning disorders. The prognosis for individuals with

acquired language disorders must be assessed according to the severity of injury or medical illness, as well as the premorbid state of the child, in each case.

Differential Diagnosis
ELD and MRELD are distinguished from each other by the presence or absence of receptive problems. Children with autism may have any or all of the characteristics of the language disorders. However, they have many additional problems including the use of language in a restricted and often stereotypic fashion rather than for communicative purposes. They also have difficulties with a wider range of interactions with persons and objects in their environment and exhibit a restricted range of behaviors. The language impairments of mental retardation, oral-motor deficits, or environmental deprivation are not diagnosed in this category, unless they are well in excess of what is expected. Language impairment due to environmental deprivation tends to improve dramatically with environmental improvement. Sensory deficits, especially hearing impairment, may restrict language development. Any indication of potential hearing impairment, no matter how tenuous, should prompt a referral for an audiologic evaluation. Obviously, hearing and language disorders can and do coexist. Some children develop an acquired aphasia as a complication of general medical illness. This condition is usually temporary; only if it persists beyond the acute course of the medical illness is a language disorder diagnosed.

Differences in Developmental, Gender, and Cultural Presentation
All communication disorders have a male-to-female predominance. In all, the prevalence of these disturbances is comparable in magnitude to many other common psychiatric disorders of childhood.

It is imperative that clinicians recognize the range of cultural and linguistic backgrounds that inform children today. The predictable variations of accent, grammar, syntax, and vocabulary that children will exhibit must not be misidentified as signs of a language disorder. In addition, children may live in multilingual environments, and their fluency in different languages must be considered.

Etiology and Pathophysiology
Genetic Factors
Many clinicians believe that communication disorders tend to “run in families,” but the extent to which this is true is unclear. No clear mechanisms of transmission have been elucidated, but a number of instances of family aggregation have been reported. At least one of these (Gopnik and Crago 1991) suggested the presence of a single dominant-autosomal gene. Tomblin (1989) reported increased concordance of language disorders among siblings. An increasing number of family studies now suggest that these disorders are familial. Prominent among these is the twin’s early development study (TEDS) in the UK (Plomin and Dale 2000). These reports cannot absolutely prove any genetic hypothesis; however, they are provocative and suggestive of a polygenetic basis. Marcus and Rabagliati (2006) have provided a thoughtful perspective on the possible contribution of “generalist” versus “modular,” that is, language-specific genes to these disorders. Plomin (2001) in an authoritative review suggests that the application of a quantitative trait loci (QTL) model may elucidate the variable pattern of transmission and presentation of these disorders. This area of inquiry is complicated not only by methodologic issues, but also by larger controversies over the degree to which specific features of language, such as grammar, arise from a “preprogrammed” genetic base. The recent work of Baker (2001) influenced by the model of Chomsky (1988) suggests that grammar in all language may be a product of an innate and limited series of “hard-wired” options.

Neurobiological Factors
Baker (1990) and others propose that communication disorders arise from at least three interrelated sets of factors: neurophysiologic (including structural), cognitive–perceptual, and environmental. The great majority of children with communication disorders give no evidence of specific CNS damage. Thus, in these children, minimal or subclinical damage has been postulated. The relative frequency of “soft” neurological signs and lateral dominance problems in this population provokes this speculation. However, at this time no clear neurophysiologic mechanisms or pathology can be correlated with these disorders, despite the appeal of this model to many physicians. Some interesting findings are emerging, however. For example, recent reports of magnetic resonance imaging (MRI) studies in stuttering (Foundas et al. 2001) have suggested anatomical differences in Broca’s and Wernicke’s areas of the left cerebral cortex in affected subjects. In a minority of children with communication disorders, a neuropathologic cause is painfully apparent. Localizable brain damage may arise from trauma, infection, vascular disease, or neoplasm. Perinatal factors such as prematurity, low birth weight, and asphyxia have also been implicated. A number of toxic agents have been associated with communication disorders, particularly lead. Recently, concerns have been raised about prenatal alcohol exposure (Abkarian 1992) and also about the physical sequelae of abuse and neglect (Law and Conway 1992).

Psychological Factors
These hypotheses relate communication disorders to various deficits in the reception, acquisition, processing, storage, or recall of different elements of communication. Work in this area has largely been pursued through a multidisciplinary model addressing children with “developmental” communication disorders. Perceptual hypotheses posit that speech or language develops improperly because of a failure of input, that is a failure of the child to perceive or process communicated information. Without proper input, proper communication cannot come about. At times, a related model of perceptual immaturity has also been proposed. This model has undeniable intuitive appeal but does not, by itself, explain why language development may not “catch up” despite age and maturation (Table 44–3). More purely cognitive hypotheses have also been proposed. Their details are beyond the scope of this chapter, but they implicate deficits in symbolization, categorizing, hierarchical processing, and related areas. The concordance between communication and learning disorders supports these hypotheses. However, not all children with communication disorders have cognitive deficits. Some authors (Friel-Patti 1992, Helmhuth 2001)
propose that there are certain language-specific abilities; this notion is invigorated by the phenomenology of Williams syndrome, in which affected individuals may have good language skills in the presence of mental retardation.

Social/Environmental Factors
This category is generally taken to refer to the psychosocial environment of the child, although general medical factors such as perinatal complications or recurrent otitis media may also be included. In this way, the category may at times be overlapped with perceptual deficits; both interfere with input. Inadequate or pathologic parent–child interaction has been associated with the rate of language acquisition, although not so clearly with eventual outcome. Other socioeconomic variables such as class, family size, income, and birth order all clearly affect the amount of verbal interaction children receive and have also been implicated. Some authors (Law and Conway 1992) have attempted to elucidate specific effects on language of child abuse, mainly in regard to syntactic form, but this is speculative at best. No definitive relationship between any psychosocial factor and the type or severity of communication disorder has been established.

Treatment
Treatment Goals
Speech and language therapy typically has three major goals: the development and improvement of communication skills with concurrent remediation of deficits, the development of alternative or augmentative communication strategies where required, and the social habilitation of the individual in regard to communication. Thus, a very great range of approaches and components must be employed in treating children with communication disorders. The speech and language pathologist (SLP) plays the most direct role in treatment of these conditions; this role is illustrated by the diagnostic treatment tree (Figure 44–2). SLPs may employ an exceedingly wide range of techniques with children. Their work, not unlike medical psychotherapy, requires both science and art. As in child psychotherapy, the participation of parents is necessary. Parent–infant work involves demonstration and modeling of language-stimulation techniques. Individual therapy can usually be begun by 3 years of age, and early initiation of therapy is frequently recommended. Individual sessions can include traditional exercises along with seemingly less structured but nonetheless carefully directed verbal and play interactions. A lay observer of a session might recognize exercises of the “Peter-piper-picked-a-peck” type as therapeutic. However, the same session might also include periods of seemingly free play or undirected conversation that, in fact, subtly model and direct the patient in the skills of speech and language. Group therapy can also be used especially in the development of language skills applied to a social context, but it should not be regarded as a low-budget substitute for individual treatment. In any treatment regimen, constant monitoring and regular reassessment are necessary.
Table 44–4  Indications for Referral for Communication Evaluation

| Language | | | | |
| --- | --- | | | |
| • The child does not use any single words by 16–18 months. | | | |
| • At 18 months, the child cannot follow simple instructions such as “Give me your shoe” or cannot point to body parts or common objects following a verbal request. | | |
| • The child does not combine words for short utterances by the age of 2 years. | | |
| • The child does not communicate with complete sentences by the age of 3 years. | | |
| • At 3 years, the child echoes parts of questions or commands rather than responding appropriately. For example, when asked “What’s your name?” The child responds, “Your name.” | | |
| • Sentence structures are still short and noticeably defective at the age of 4 years. | | |
| • At 4 years, the child uses words incorrectly or frequently substitutes an associative word for the intended word. For example, the child may say “cut” for “scissors” or “dog” for “cow.” | | |
| Articulation | | | |
| • The child is embarrassed or disturbed by his/her speech at any age. | | |
| • The child is omitting, substituting, or distorting any sounds after the age of 7 years. | | |
| • At the age of 6 years, the child is still unable to produce many sounds. | | |
| • The speech is difficult to understand at the age of 4 years. | | |
| • At the age of 6 years, the child is still unable to produce many sounds. | | |
| • The child is omitting, substituting, or distorting any sounds after the age of 7 years. | | |
| • The child is embarrassed or disturbed by his/her speech at any age. | | |
| Voice | | | |
| • The voice is hoarse, harsh, breathy, or of poor quality. | | |
| • The voice is always too loud or too soft. | | |
| • The pitch is inappropriate for the child’s age or sex. | | |
| • Pitch breaks occur frequently. | | |
| • The voice is hyponasal or hypernasal. | | |
| • There is nasal air emission, a nasal “rustle,” snorting, or a nasal grimace during speech. | | |
| Stuttering | | | |
| • The parents have expressed a concern about stuttering. | | |
| • The child has an abnormal number of repetitions, hesitations, prolongations, blocks, or disruptions in the natural flow of speech. | | |
| • The child exhibits tension during speech. | | |
| • The child avoids speaking situations due to a fear of stuttering. | | |
| • The child considers him/herself to be a stutterer. | | |

as is ongoing support to parents who must reinforce the treatment at home. Similarly, regular reconsultation with other professionals from the multidisciplinary team may be required (Table 44–4).

Somatic Treatments

Drug therapy for these disorders remains at best controversial. The psychiatrist will be required to treat associated conditions, and communication performance may improve with such treatment.

Psychosocial Factors

Individual and family psychotherapy may be a useful augment in reducing the stress these children encounter.

Issues in the Clinician–Patient Relationship

The psychiatrist may have a major role in the treatment of communication disorders. These children and their families may present for psychotherapy or other treatment for disorders based on or related to communication problems. Thus, the psychiatrist may, in the first place, be a case finder or a case manager, facilitating the evaluation and treatment of these disorders by a multidisciplinary team. The demonstrated psychiatric comorbidity of these disorders will necessitate the psychiatrist’s involvement on many levels, both as a clinician primarily treating a child and as a therapist, counselor, and agent of advice and support for the entire family. Psychotherapy does not directly address language disorders, although older literature has cited improvement in stuttering following family and individual treatment. The psychotherapist must, in any event, be sensitive to the manner in which communication disorders can affect or interfere with the therapeutic process. Nonverbal augments or prompts should be sensitively provided to children who need them.

Treatment-Refractory Patients

Outcome studies of communication therapy, especially for the language disorders, have often been complicated by multiple theories of language development, diagnostic and methodologic variations, lack of standardization of therapeutic techniques, and comorbidity. Thus, the literature in this area is relatively sparse and not always conclusive. Like the outcome of psychotherapy this is a difficult area to study. The quality of work in this area has been enhanced by the development of empiric measures such as the therapy outcome measure (Roulstone et al. 2004).

Nonresponse to initial treatment may be common, requiring patience and persistence. It is important to note in assessing these issues that, even when communication therapy does not lead to apparent improvements in language beyond developmental improvements, it may still facilitate the child’s use of extant language for environmental and self-control (Goldstein and Hockenberger 1991). ELD and MRELD patients with comorbid phonation disorder have a poorer prognosis (Lewis and Fairbairn 1992).

Special Factors Influencing Treatment

Academic Comorbidity

It should come as no surprise that children with communication disorders, and especially with language disorders, are academically vulnerable. Education, as we know it, especially for younger children, is largely based on language. Bashir and Scavuzzo (1992) suggest that these children’s vulnerability arises from the persistence of these disorders in the face of the continuing need for language in school. Moreover, even if a language disorder has been remediated, children may have failed in the meantime, and it is immensely hard for many children in many schools to succeed again, once they have failed for any reason. A further complication is the comorbidity of LD in these children. In all, some 50–75% of children with language disorders will
have persistent academic problems (Aram and Hall 1989). They tend to learn less at any given time and learn more slowly than their peers (Shaywitz 1989). These children need ongoing comprehensive special educational services and regular reevaluation of their educational needs.

**Demographic and Cultural Issues in Treatment**

The relationship of socioeconomic status (SES) with the occurrence of communication disorders is not altogether certain. Many studies indicate a positive correlation between communication disorders and low SES, but other work suggests that this correlation is weak at best. The need for clinicians to avoid regarding variations in accent and dialect as pathological has been cited. Very little empirical literature on cultural variations in communication therapy is extant. McCrary (1992) and others have pointed out the need for cultural sensitivity in treatment, citing the efforts of ASLHA in this area.

**Phonological Disorder**

**Diagnosis**

**Definition and Diagnostic Features**

This condition was formerly known as articulation or developmental articulation disorder. It is characterized by an individual's failure to use speech sounds appropriate for one's developmental level and dialect. The affected individual may substitute one sound for another (e.g., /l/ for /r/), omit certain sounds entirely, or exhibit other errors in organization, use, or production of sounds. By definition, in DSM-IV-TR these difficulties interfere with social, academic, or occupational functions. The symptoms may occur during development without discernible cause or they may be related to CNS, motor, or sensory dysfunction or to environmental deprivation. In the latter cases, speech difficulties must be in excess of those usually associated with the particular problem for the diagnosis to be made. This condition ranges in severity from very mild problems to severe disorders, which render speech totally unintelligible.

This condition is characterized by persistent errors in the production of speech. These include omission, substitution, or distortion of sounds. Omissions include single or multiple sounds: “I go o coo o the but” (I go to school on the bus) or “I re a boo” (I read a book). Substitutions include w/l, t/s, w/r, and d/g: “I taw a wittle wedadio. It pwayed doud music.” A common distortion is lisping. A frontal lisp leads to an /s/ sound resembling /th/. A lateral lisp, with sound coming from the sides of the mouth, leads to a “slushy” /s/ sound: “Shuffering shnakes!” Defects in the order of sounds or insertions of extraneous sounds may also be heard: “cath” for “cats.” The occurrence of these errors is persistent but not constant. Baker (1990) points out that “conditioning factors” such as the location within a word or the rate or length of a statement may determine whether a phonologic error is produced. Only some sounds are usually affected, as for example, in lisping the misarticulation of sibilants. Some articulation errors are expected in early childhood, especially involving sounds that are usually mastered at a later age (in English /l/, /r/, /s/, /z/, /θ/, and /ð/); these errors are not regarded as pathological unless they persist and result in adverse consequences to the individual. It is estimated that 90% or more of children have mastered the more difficult sounds by the age of 6–8 years.

**Epidemiology**

PD occurs in approximately 2% of 6- and 7-year-olds, but this prevalence falls to 0.5% by the age of 17 years.

**Comorbidity**

Children with this problem may present with clearly associated causal factors such as anatomic malformations, neurological diseases, or cognitive disorders, although most do not. They do have a higher prevalence of language disorders, with all their associated problems, than do normal controls. Even if they are free of language disorders they are still more likely to have ADHD, although probably not as commonly as do children with language disorders. Children with PD, especially when associated with stuttering or hyperactivity, are prone to social discrimination and isolation with subsequent consequences.

**Course**

The course of PD is much more encouraging than those of other communication disorders. Milder cases may not be discovered until the child starts school. These cases often recover spontaneously, especially if the child does not encounter adverse psychosocial consequences because of his/her speech. Severe cases associated with anatomic malformations may at times require surgical intervention, and its course and outcome depend on its success. Between these two extremes are children who gradually improve, often to the point of total remission, and whose improvement may be accelerated by speech therapy.

**Differential Diagnosis**

Some articulation errors are expected in early childhood, especially involving sounds that are usually mastered at
a later age (in English /l/, /r/, /s/, /z/, /th/, and /ch/); these errors are not regarded as pathological unless they persist and result in adverse consequences to the individual. It is estimated that 90% or more of children have mastered the more difficult sounds by the age of 6–8 years. Problems limited to voice alone are included under CDNOS.

Differences in Developmental, Gender, and Cultural Presentation

The male-to-female predominance in communication disorders and the need for clinicians to avoid regarding variations in accent and dialect as pathological have been cited. Very little empirical literature on cultural variations in communication therapy is extant. McCrarry (1992) and others have pointed out the need for cultural sensitivity in treatment, citing the efforts of ASLHA in this area. These conditions should be distinguished from the normal dysfluencies that occur among young children. For example, misarticulation of some sounds, such as /l/, /r/, /s/, /z/, /th/, and /ch/, is common among preschoolers and resolves with age. As with the language disorders, these diagnoses are given in the case of motor or sensory deficit, mental retardation, or environmental deprivation, only if the disorder is much more severe than expected in these conditions.

Etiology and Pathophysiology

The general range of genetic, neurobiological, and psychological factors that influence ELD and MRELD are felt to be influential in PD as well. Review of social and environmental factors reveals a considerable amount of overlap, with potentially complex interrelationships of causality and concurrence. Clinical observation seldom, if ever, suggests a unitary causality of communication disorders in real patients. Thus, these conditions in most patients are ultimately described as multifactorial. The clinician should be aware that many or all of the factors cited may be present in any communication-disordered patient and may have complex effects on communication as well as other aspects of the patient's life.

Treatment

Treatment goals for PD are comparable to those for other communication disorders, heartened by the generally good prognosis of this condition. Somatic treatments are not appropriate for this condition, although they may be employed for comorbid psychiatric disorders. These patients may encounter the same psychosocial factors and present similar issues in clinical relationships as do those with other communication disorders.

Special Factors Influencing Treatment

Children with PD may have persistent academic problems. These are generally less severe than those with language-disordered children, unless both types of disorders are present. Lewis and Fairbairn (1992) reported mild but persistent problems with reading and spelling in individuals with PD, even into young adulthood. Subjects tended to steadily improve over time, however. Although most of the subjects and all the adolescents and adults were considered normal speakers, they tended to show subtle phonological problems on specialized tests. Children with an associated language disorder fared less well.

Stuttering

Diagnosis

Definition and Diagnostic Features

Stuttering is one of the most commonly recognized disorders of speech. Some occurrence of the symptoms of stuttering is normal in the earlier stages of development, and the condition is properly diagnosed only when the symptoms are perceived to be in excess of what is developmentally expected. Similarly, since occasional symptoms appear in the speech of nearly all persons, the diagnosis is not made unless the disturbances interfere with social, academic, or occupational functioning. The condition may be associated with motoric or sensory deficits; when this is the case, the diagnosis is made only when symptoms exceed those expected with these problems. The characteristic symptoms of stuttering, as shown in the DSM-IV-TR criteria for stuttering, are disturbances in fluency (such as repetitions of sounds, syllables or words, interjections, and circumlocutions) and in time patterning (sound prolongations, broken words, and blocking). “Cluttering,” the disturbance in rate and length of speech noted in DSM-III-R, is subsumed in DSM-IV-TR under CDNOS, or ELD.

The familiar symptoms of this disorder are noted in section A of its DSM-IV-TR criteria. Stuttering is the communication disorder most easily recognized by both the lay public and the physicians. It varies in severity among individuals. It may be more or less evident in different

</table>

situations and may vary over time. It is typically most severe when the affected child is stressed or anxious, and especially when communication is expected. Children who stutter can sing or talk to themselves without difficulty. Because of its often gradual onset, children are at first frequently not aware of its presence. Over time they may become more anxious and withdraw from conversation, as the degree of social discrimination they experience increases. Stuttering may be accompanied by various movements that may seem either to express or to discharge anxiety, such as blinking, grimacing, or hyperventilation. Sometimes children who stutter may attempt to stop momentarily by slowing down or pausing in their speech, but this is frequently unsuccessful and leads to an exacerbation. Thus, a pattern of habitual fear and avoidance emerges.

Assessment
Assessment of this disorder is conducted through a comprehensive speech and language evaluation, as described earlier.

Epidemiology
Stuttering occurs in approximately 1% of children aged 10 years and younger, declining modestly to 0.8% in later adolescence. All communication disorders have a male-to-female predominance; that of stuttering is as high as 3:1.

Comorbidity
There is much less literature extant addressing the comorbidity of stuttering compared to other communication disorders. Other communication disorders are more frequently reported in those with stuttering rather than in normal controls. Stuttering is frequently accompanied by many linguistic mechanisms and social maneuvers to avoid its manifestation. Conversely, it appears more frequently and intensely in affected individuals when they experience anxieties or stress. The literature is replete with anecdotal and biographical accounts of the social and occupational discrimination, disappointment, and low self-esteem faced by persons with this condition. The negative stereotype of stutterers in society is well documented. They have been mocked in drama and cinema (including cartoons) for centuries and all too often are regarded as intellectually impaired.

Course
Stuttering usually appears in early childhood, as early as 2 years of age, and frequently has its onset around the age of 5 years. The onset of stuttering is typically regarded as gradual, with repetition of initial consonants or first words or phrases heard in the beginning. However, a study by Yairi and colleagues (1993) suggested that often early stuttering takes on a moderate-to-severe form and that identification of problems in this period has been affected by parents’ tendency to postpone professional consultation. Children are generally not aware of this condition in themselves until it is pointed out to them by others. The disorder can wax and wane during childhood. By early adolescence it abates spontaneously in some cases, and from 60% to 80% of individuals eventually recover totally or to a major extent. DSM-IV-TR asserts that spontaneous recovery typically occurs before the age of 16 years. Stuttering may persist into adulthood, often leading to adverse social and occupational consequences.

Differential Diagnosis
These conditions should be distinguished from the normal dysfluencies that occur among young children. For example, misarticulation of some sounds, such as /r/, /l/, /s/, /z/, /l/, and /ch/, is common among preschoolers and resolves with age. As with the language disorders, these diagnoses are given in the case of motor or sensory deficit, mental retardation, or environmental deprivation, only if the disorder is much more severe than expected in these conditions. Problems limited to voice alone are included under CDNOS.

Differences in Developmental, Gender, and Cultural Presentation
The male-to-female predominance of communication disorder and the need for clinicians to avoid regarding variations in accent and dialect as pathological have been cited.

Etiology and Pathophysiology
Genetic Factors
A genetic basis for stuttering has been proposed for many years. The Yale Family Study of Stuttering (YFSS) suggested that 15% of first-degree relatives of stutterers are affected at some time in their lives (Kidd 1983). A concordance of 77% in identical twins and 32% in fraternal twins has also been reported (Howie 1981). These reports were subsequently confirmed by other studies (Yairi et al. 1996, Andrews et al. 1991). Recent linkage studies implicate several susceptibility loci and support a hypothesis that the genetic component to stuttering has significant sex effects (Suresh et al. 2006).

Neurobiological Factors
The special phenomenology of stuttering suggests the possibility of dysynchrony between phonation and articulation, as reported by Perkins (2001). The neurobiologic aspects of the other communication disorders are also considered relevant to this condition. Techniques including qEEG, PET, and fMRI are being employed to elucidate the role of hemispheric asymmetry (Ozge et al. 2004), dysfunctions of basal ganglia circuitry (Alm 2004), and many other factors.

Psychological Factors
In the past, various psychodynamic etiologies have been proposed for stuttering; these have been more stigmatizing than illuminating. The association between the exacerbation of stuttering and stress is well known, however. Work in this area has frequently confounded predisposing, triggering, and maintaining factors (Schulze and Johannsen 1991).

Social/Environmental Factors
Review of these influences reveals a considerable amount of overlap, with potentially complex interrelationships of causality and concurrence. Clinical observation seldom, if ever, suggests a unitary causality of communication disorders in real patients. Thus, these conditions in most patients are ultimately described as multifactorial. The clinician should be aware that many or all of the factors cited may be present in any communication-disordered patient and may have
complex effects on communication as well as other aspects of the patient’s life.

**Treatment**

**Treatment Goals**
The treatment of stuttering has provoked special interest in recent years, particularly as its adverse consequences in adulthood have been recognized. Approaches to this problem address both the mechanics of speech and the associated attitudinal and affective patterns. Guitar (1985) notes that therapists attempt to modify speech rhythm and speed, leading subjects to regularize rhythm, and as a temporary measure prolong their speech. Thus, patients might be heard speaking in a slow, drawnout, sing-song fashion. Much attention is also directed to respiration, airflow, and “gentle” onset of phonation. This necessitates a multimodal approach (Healey et al. 2004) and family involvement.

**Somatic Treatments**
In the 1960s and 1970s, some reports of haloperidol treatment for stuttering emerged. However, enthusiasm was tempered by recognition of this agent’s side effects (Andrews and Dozza 1977), and it is very seldom used for this condition today. There have been occasional reports of treatment of stuttering in the past with tricyclic antidepressants and, more recently, selective serotonin reuptake inhibitors (SSRIs) (Stager et al. 1995, Schreiber and Pick 1997). The rationale for these treatments appears to be a hypothetical connection between stuttering and other compulsive behaviors. These accounts are provocative but do not suggest any real indication for these medications for stuttering alone. A recent case report (Van Wattum 2006) and earlier studies (Maguire et al. 2000) have suggested the possibility that risperidone, a novel antipsychotic, might be useful, but its potential utility must be weighed carefully against its known adverse effects. Moreover, stuttering related to olanzepine and clozapine has been reported (Bär et al. 2004).

**Outcome**
The literature on the outcome of treatment for stuttering is somewhat more complete than for the other communication disorders, since symptoms of this disorder can be readily quantified by electronic and other means. Success rates for various treatments of up to 70% have been reported, although with varying follow-up periods and relapse rates (Guitar 1985). Some SLPs specialize in the treatment of this disorder (Rafuse 1994). As in all communication disorders, the psychiatrist may have a major role in the treatment of children and their families.

**Communication Disorder Not Otherwise Specified**
This category includes disorders that do not meet criteria for other specific communication disorders or do so incompletely. DSM-IV-TR cites voice disorders of pitch, loudness, quality, tone, or resonance, as an example. The presence of this heterogeneous category reflects the multifactorial and mixed nature of communication disorders in

---

**DSM-IV-TR Criteria**

### Communication Disorder Not Otherwise Specified

This category is for disorders in communication that do not meet criteria for any specific communication disorder; for example, a voice disorder (i.e., an abnormality of vocal pitch, loudness, quality, tone, or resonance).

classmates. By the age of 9 years her speech was regarded as entirely normal by her parents and teachers, and she was functioning well in all spheres. However, she continued to have subtle phonological findings as an adolescent.

Clinical Vignette 2 • Receptive–Expressive Language Disorder

GB, a 6-year-old boy, who lived with his parents and several siblings in an isolated area, was referred by a family physician at a rural health center who felt that he might have autism. He was a child of normal appearance and good general health who exhibited no speech whatsoever. The family physician had tested his hearing and believed that it was adequate; his parents agreed, since they found that he had always been able to respond to a wide range of sounds, from bird calls to thunder. They had deferred medical attention until GB was identified by the regional school as a student entitled to special educational services. The parents were medically unsophisticated but attentive and devoted. They felt that GB was “slow,” but that little could be done for him, and that the family would always take care of him. They felt that they could communicate with him with gestures and reported that his older siblings were especially adept at this. The family traveled to a university diagnostic center. Psychiatric evaluation disclosed a cheerful, interactive child, who could engage in some mimetic play and was sensitive to the moods of others. On psychological evaluation, GB exhibited low average cognitive ability on some nonverbal instruments and some receptive ability when given nonverbal prompts. Speech and language evaluation, along with family observation by all members of the diagnostic team, disclosed a severe MRELD for spoken language. However, GB and his siblings had developed a sign language that enabled them to communicate needs and wants, as well as to describe affects and comment, etc., on many activities in their home. They were referred as a group to a SLP at their county seat. The pathologist was able to teach GB Ameslan (standard sign language), and eventually he also developed a limited oral vocabulary. Other team members were able to document nearly average nonverbal intelligence and rule out other major psychopathology. Nonetheless, GB’s school district proposed placing him in a classroom for severely mentally handicapped children. The psychiatrist was able to offer supportive psychotherapy to the parents, who had been devastated by the proposal, while the liaison special educator set about locating a class for language-disabled children in an adjacent county. GB was able to enter this class after the local school district was convinced of its educational and legal advisability. He did well there and subsequently completed a vocational program in automobile mechanics. As a late adolescent, he still has a limited vocabulary and reads at a sixth-grade level but can follow mechanical and schematic diagrams well and relates appropriately with his classmates.

many children who may have multiple mixed symptoms of more than one disorder. Its treatment requires addressing of all the components of the various disorders represented.

Introduction
The pervasive developmental disorders (PDDs) represent a class of developmental disorders characterized by impairments spanning multiple domains of functioning. Five disorders fall within the class of PDDs and will be discussed in this chapter: autistic disorder, Asperger's disorder (AD), pervasive developmental disorder—not otherwise specified (PDD-NOS), childhood disintegrative disorder (CDD), and Rett's disorder (RD). The term “autism spectrum disorder” (ASD) is usually reserved for the first three disorders (autistic disorder, AD, and PDD-NOS), as evidence suggests these disorders share common phenotypic and etiologic features distinguishing them from RD and CDD. The ASDs are characterized by impairments in social and communicative abilities, along with rigid and repetitive patterns of behavior (e.g., motor mannerisms, resistance to change, and idiosyncratic interests and preoccupations). Social disability is considered the hallmark and, diagnostically speaking, most germane feature of the disorders. The disorders vary in terms of severity, age of onset, presence of communicative impairments, and repetitive and restricted interests, but all ASDs require evidence of impairment within the domain of social behavior for diagnosis. ASDs have become a focus of international, professional, and popular attention in recent years. A study by the Center for Disease Control and the Autism and Developmental Disabilities Monitoring Network estimates the prevalence of ASDs in the United States to be 1 in 150 people (2007); once considered a rare disorder, ASDs are now certain to be encountered by practicing psychiatrists. Significant strides have been made in terms of psychosocial interventions; these therapies ameliorate symptoms primarily through compensatory strategies addressing areas of vulnerability. Psychopharmacology offers a promising treatment approach, but the effects of currently available medications are limited to associated features, such as aggression or irritability, without directly altering the core social impairments of the disorders. These advancements in psychosocial and somatic approaches have improved outcome for individuals with PDDs. Research in the genetic and neurobiological underpinnings of the PDDs has already been fruitful, and it is hoped that continued research can move the field closer toward biomarkers for early detection and biologically based interventions.

Autistic Disorder

Definition and Diagnostic Feature
Autistic disorder is the most extensively studied and best understood of the ASDs. “Autistic disorder” is the descriptor used in the DSM, but, in practice, the terms, “autism,”
“childhood autism,” “infantile autism,” and “early infantile autism” are used synonymously. The condition is characterized by marked and sustained impairment in social interaction, communication, and restricted or stereotyped patterns of behaviors and interest evident by 3 years of age. See DSM-IV-TR criteria for Autistic Disorder (American Psychiatric Association 2000).

Diagnosis of autism requires a minimum of six behavioral criteria, at least two from the domain of social impairment and one from each of the other two areas of impairment (communication and restricted/repetitive behaviors). Contrasting the disorder from more general intellectual impairment, these social and communicative deficits are considered with respect to overall developmental level. In children with global cognitive impairment, social and communicative skills are typically commensurate with broad intellectual functioning; in autism, these areas of function represent selective weakness. Thus, it is always vital to evaluate symptoms of autism in the context of broad developmental level.

Social disability represents the earliest appearing and most focal impairment in autism and the other ASDs. One of the early appearing manifestations of the disorder is reduced interest in interpersonal interactions. In typical development, children are drawn toward other human beings from birth; infants show strong preferences to look at human faces and display a characteristic bias toward gazing to the eyes. This pattern persists throughout development, and, even in adulthood, the eyes remain the most important focus of the human face, as they provide the richest information about affect and attention. Parents of children with autism often note that, even in infancy, these children fail to demonstrate this gravitation toward other people, instead preferring to explore objects in their environment (often in atypical, repetitive ways). This disinterest in other people manifests as reduced social overtures, less looking to the face of others and using eye contact communicatively, and decreased joint attention behaviors. Joint attention refers to actions intended to direct or draw the attention of another person. For example, a child might look to his mother, look to an interesting object in the environment, and then look back to his mother to gauge her reaction to it (when a child uses joint attention to ascertain the affective valence of another, this joint attention behavior is called social referencing). Children with autism are much less likely to attempt to use gestures or language for social purposes, or to show things or comment on things to parents, than for practical purposes, such as requesting a

</table>

among high-functioning and more verbal children with autism. They tend not to seek social interaction out. A third group, described as passive, may respond to social overtures. Children are aloof, isolated from interpersonal interaction and do not drive to communicate. Although these dysfunctions are evident at the most basic levels of social interaction, individuals with autism also display impairments in higher order aspects of social interaction. These difficulties have been interpreted as reflective of impairment in social cognition. They are poor at empathizing and taking on the perspective of others (Klin 2000) and possess an underdeveloped theory of mind, that is, the ability to appreciate another’s mental states as distinct from one’s own (Baron-Cohen 1983).

Despite the fact that impaired social interaction, the hallmark of ASDs, is found in all children with autism, degree of impairment and style of interaction vary widely from child to child. Wing and Gould (1979a) developed a system for classifying these interpersonal styles. Many children are aloof, isolated from interpersonal interaction and unlikely to initiate or respond to social overtures. Children in this class, however, may enjoy interactions of a physical or rough-and-tumble nature. A second class of children is described as passive. Although these children may respond to social interaction, they tend not to seek it out. A third descriptive category of social interaction, often observed among high-functioning and more verbal children with autism, is an “active but odd” presentation. In this case, the child may seek social interaction but do so in an awkward, atypical fashion.

Language is usually significantly impaired in individuals with autism. It has historically been estimated that as many as half of individuals with autism never develop functional speech; but this proportion is decreasing due to improved detection and intervention procedures, along with recognition of high-functioning forms of the disorder (Tager-Flusberg et al. 2005). Nevertheless, language impairments represent a core phenotypic feature, with delays in the acquisition of language representing the most frequent presenting complaint. Usual patterns of language acquisition (e.g., playing with sounds and babbling) may be reduced in frequency or altogether absent. Children with autism commonly manipulate a parent’s hand (as if the hand were a disembodied tool) instead of making more conventional requests. In contrast to children with language impairment alone, children with autism display an apparent reduced drive to communicate and tend not to compensate through nonverbal means, such as gesture or eye contact.

When individuals with autism do develop speech, their language is atypical in several respects (Paul and Sutherland 2005). They frequently display immediate or delayed echolalia, or repetition of previously heard speech. Immediate echolalia often takes the form of repeating statements or questions uttered to the child and has been considered the child’s attempt to “respond” despite lacking comprehension of the verbiage or the ability to formulate an appropriate response. Immediate echolalia is often observed in typical language development as a tool for acquiring speech; it follows that it is considered a positive predictor for functional language development in children with autism. Delayed echolalia is also common and may manifest as repeating snippets of previous conversations or movie dialog. These utterances may be nonreciprocally and noncommunicative in nature or may be incorporated into functional language. For example, a child might repeat a parent’s admonishment aloud every time they become anxious that they have done something wrong or use lines from movie dialog appropriately in real-life situations analogous to the movie scene. The term “stereotyped speech” refers to the application of these rote, scripted speech patterns in this fashion. Because of the rote and inflexible manner in which speech is learned and utilized, children with autism often produce idiosyncratic patterns of speech that are functional but odd. For similar reasons, children with autism often reverse pronouns, commonly referring to themselves in the second person.

The syntax and morphology of language are typically intact in individuals with autism who develop speech. However, they have particular difficulty with social uses of language (pragmatics). Thus, humor and sarcasm are often misconstrued as a person with autism may fail to appreciate the speaker’s communicative intent and interpret the jest literally (Dennis et al. 2001). Indeed speech in individuals with autism tends to be excessively concrete, both in terms of production and comprehension. The prosody of individuals with autism is usually inappropriate, with flat intonation and halting pacing, sometimes described as “robotic.” Deficits in pragmatic communication, particularly the ability to have a back-and-forth conversation, are prevalent. The language and communicative deficits in autism differ from those characterizing pure language impairments in their understanding and use of language.
focal social difficulties, as well as the severity of language delays (Paul and Sutherland 2005). Research has not yet clarified whether pragmatic impairments reflect difficulty with the abstraction of these linguistic constructions or disregard of their purely social utility.

Impairments in play are included with the symptom class of impaired communication. Children with autism show reduced interest in imaginative or pretend play. This co-occurs with unusual ways of using toys, in particular exploring the physical properties of objects rather than using them for intended functional and symbolic purposes. For example, rather than using a toy car as such, a child with autism might hold the car upside down and repeatedly spin its wheels. Often children with autism will peer closely at such an object, sometimes moving it across their field of vision or looking at it from the corner of their eye.

These behaviors appear geared toward basic forms of sensory self-stimulation, and, more generally speaking, children with autism are commonly reported to display both hyper- and hyposensitivity to sensory stimuli. Children with autism may be oversensitive to sounds, for example, reacting strongly to the sound of a vacuum cleaner. There may be heightened sensitivity to touch (tactile defensiveness), though many children display increased pain threshold. Many children enjoy vestibular sensations such as spinning or swinging. Children with autism often smell or taste objects in unusual ways. Indeed, *pica*, or the placement of inedible objects in one’s mouth, is common in individuals with autism.

Individuals with autism often exhibit pronounced motor stereotypes. These behaviors can include hand flapping or rapid finger movements (often in front of the eyes), body rocking, or tensing their extremities while jumping up and down. Stereotypes, though not unique to autism and seen in other disorders, including severe mental retardation and sensory impairments, represent a common and distinctive feature of the disorder, often emerging around age 3. They appear to represent a form of self-regulation and often are most evident during periods of heightened arousal, such as excitement or apprehension. These behaviors often abate in adolescence and adulthood, particularly among high-functioning individuals. Some children with autism have been reported to display *echopraxia*, or the imitation of other’s motor movements without comprehension of intent or function. Otherwise, the fine and gross motor function of children with autism tend to be appropriate to their developmental level. Increased level of baseline motor activity is common in autism, particularly in preschool years, though passivity and reduced interest in exploring the environment can also manifest as decreased levels of physical activity. Self-injurious behavior, such as biting or striking, can occur in autism, especially among low-functioning children. Head banging is also common, particularly among the most intellectually impaired. Aggression against other people can also be observed. This usually stems from frustration with an inability to communicate effectively coupled with poor understanding of the impact of aggression on other people, rather than from malicious intent. As such, the appropriate intervention is to understand the elicits of these behaviors and the function they serve for their child and then modify the environment and teach replacement behaviors so as to obviate the need for aggression as a communicative tool.

Children with autism often have difficulty in tolerating change and variation in routine, or, as termed by Kanner, an “insistence on sameness.” For example, a minor change in routine, such as driving an alternate car or using an alternate entrance to a building, might be responded to with significant distress. Parents often report that their child performs activities in methodological, specific ways. Furthermore, the child may display interest in a repetitive activity, such as ripping up pieces of paper or repeatedly dropping objects into a heat vent.

A majority of children with autism display cognitive impairment. It has been estimated that approximately 75–80% of individuals with autism are classified as intellectually disabled, with about 30% falling in the mild to moderate range and 45% in the severe to profound range. Comparable to typical children, IQ scores are relatively stable and predictive of outcome (Klin et al. 2005c). Current trends toward earlier detection and intervention, along with increased recognition of higher functioning forms of the disorder, are likely to decrease the proportion of individuals with autism with intellectual disability. On measures of cognitive ability, children with autism tend to display deficits in abstract reasoning, verbal concept formation, and integration skills, as well as tasks involving social insight. In contrast, relative strengths are usually observed in the areas of rote learning and memory skills and visual-spatial problem solving. Individuals with autism display a bias toward perceiving and processing information at the level of local details rather than the global level, or the “big picture”; they have difficulty “seeing the forest for the trees.” This processing bias is reflected in greater success on parts-to-whole tasks, rather than tasks requiring them to process a *gestalt*. Consistent with the prevalent impairment in language, children with autism also tend to display stronger performance on measures of nonverbal ability relative to verbal ability. A small percentage of individuals with autism, approximately 10%, display savant skills, or specific abilities that dramatically exceed their own broader intellectual ability or the abilities of their typically developing counterparts. These skills may take the form of musical or drawing ability or exceptional feats of memory, such as the ability to name days of the week corresponding to dates several years in advance (“calendar calculators”; Hermelin 2001). A common isolated strength in children with autism is facility in decoding letters and numbers, or *hyperlexia* (Newman et al. 2006).

Children with autism often display disturbances in patterns of sleeping and eating. They may sleep in idiosyncratic patterns with recurrent awakening at night for long periods; among lower functioning individuals, this can present a safety risk as these children are then unsupervised as others in the house remain asleep. Eating disturbances may involve seeking or avoiding particular foods based on texture, color, or smell. Many children with autism resist all but a limited repertoire of foods and refuse to try new foods.

Poor affect modulation and displays of emotions inconsistent with contextual events are also seen in autism, including abrupt mood changes and laughing for no apparent reason. Temper tantrums are common, particularly in reaction to demands and unexpected changes in routine. Higher functioning individuals may display intense anxiety in social situations; they may also develop depression in adolescence, resulting from negative social experiences over the years and augmenting insight into their own social limitations.
History of the Diagnostic Concept

The diagnostic category, “autism,” dates to 1943, when Leo Kanner described 11 cases of “autistic disturbances of affective contact.” These children failed to relate to other people from very early in life and showed unusual patterns of communication (e.g., echolalia and pronominal reversal). Moreover, they responded in atypical ways to their environment, engaging in repetitive and ostensibly unproductive actions with objects and exhibiting a strong preference for sameness in routine and physical environment. Kanner provided a developmental context for his observations and emphasized the centrality of deficits in social relatedness. Though many of Kanner’s original descriptors have been incorporated into current diagnostic conceptualizations of the disorder, several of his statements contradict current understanding of autism. Kanner’s description suggested that children with autism possess intact intellectual ability, but subsequent evidence has shown that cognitive impairment tends to co-occur with autism. Kanner also erroneously speculated that autism might develop secondary to anomalous parental care and might be biased toward more educated or affluent families. Subsequent research demonstrated both of these points to be false; autism is distributed equivalently across socioeconomic strata and is not attributable to pathological parenting.

Kanner’s use of the term “autism” referenced Bleuler’s use of the term to refer to self-centered thinking in schizophrenia. Though now understood to have distinct psychopathological origins, the negative symptoms of schizophrenia (social withdrawal, blunted affect) resembled some of the social symptoms of autism. Although Kanner’s articulation of the phenomenology of autism distinguished it from childhood schizophrenia, perhaps due to the overlapping terminology or perhaps due to the severity of dysfunction, a relationship between the disorders was mistakenly assumed for years. The first (American Psychiatric Association 1952) and second editions (American Psychiatric Association 1968) of the Diagnostic and Statistical Manual of Mental Disorders did not recognize autism as a distinct disorder, viewing it instead as a form of childhood schizophrenia. Progress toward distinguishing the two disorders resulted from studies of large groups of “psychotic” children, who were observed to fall into early and late onset groups. The early onset group (prior to approximately 6 years of age) tended to exhibit the characteristics that had been described by Kanner. Conversely, children with later onset “psychosis” (after age 5 or 6) presented with more prototypically positive symptoms of schizophrenia (e.g., delusions, hallucinations). These early versus late onset psychoses mapped onto current conceptualizations of autism and childhood schizophrenia, respectively. Observation of familial co-occurrence also suggested that the disorders were distinct.

In 1978, Rutter provided a more viable operational definition of autism. He described social delay and deviance independent of mental retardation, communication problems without respect to intellectual function, and atypical behaviors (stereotyped movements and mannerisms) with onset prior to 30 months. This definition, along with an increasing body of research on autism, provided groundwork for inclusion of the disorder in the DSM-III (American Psychiatric Association 1980) in the newly created taxon of PDDs. The disorder was termed, “infantile autism” to emphasize its early onset. Criteria for the condition were monothetic and most germane to younger children with autism; “residual infantile autism” was included to describe individuals who had been diagonsed with infantile autism but no longer met diagnostic criteria. This diagnostic conceptualization was criticized for its lack of consideration of developmental factors, and a developmental emphasis was addressed in DSM-III-R (American Psychiatric Association 1987). In
this revision, the condition was described by detailed criteria grouped into three categories: social impairment, communication, and repetitive behaviors. Under the newly introduced system of multiaxial assessment, the condition was placed on Axis II. Only two diagnoses, autistic disorder and PDD-NOS, were included in the PDDs in DSM-III-R.

The current diagnostic criteria (see DSM-IV-TR criteria for Autistic Disorder) were first published in DSM-IV (American Psychiatric Association 1994). These criteria were based on the results of a large field trial, spanning multiple international sites that examined appropriateness of diagnostic conceptualization. The diagnostic criteria preserved the conceptual triad of impairments, while making an age of onset requisite for the diagnosis. DSM-IV-TR diagnostic criteria also introduced consistency with internationally utilized criteria for the PDDs, as reflected in the 10th edition of the International Classification of Diseases (World Health Organization 1992). In publishing of the DSM-IV-TR, the PDDs were returned to Axis I.

Assessment

Diagnostic assessment of autism and related conditions has traditionally been made according to clinical judgment of the presence of DSM-IV-TR criteria. Diagnostic evaluation entails a thorough developmental history, emphasizing early social development (e.g., interest in others, eye contact and joint attention behavior, atypical or repetitive behaviors, and onset and nature of communication). In conceptualizing a diagnosis of an ASD, the practitioner should attempt to verify that symptoms have been stable and evident since early childhood. In addition to an exhaustive developmental history, direct observation of the child is requisite to assess social and communicative characteristics, as well as the presence of preoccupations or atypical behaviors. Ideally, observation should occur across settings, including the clinic’s reception area (e.g., contacts with other children or with family members), the hallways (e.g., how the child interacts initially with the examiners), and during a face-to-face examination. Often, the social disability in ASD is most pronounced during periods when social expectations are unclear. It is therefore important to interview the child without providing the support characteristically provided by adults interacting with children with special needs. This can include volunteering information about oneself (to see if a child asks for clarification), waiting out awkward pauses, and asking open-ended questions. Topics of inquiry should include social relationships, interests, use of leisure time, self-awareness, insight into other people’s intentions and beliefs, and understanding of figurative language. Considering the likelihood of relative proficiency interacting with adults among high-functioning individuals, collateral information from educators and parents about behavior in social settings with peers offers extremely useful additional information. Other areas of inquiry should focus on obsessive, compulsive, and ritualized behaviors, as well as the presence of symptoms of anxiety and depression. The patient’s thought processes and reality testing should also be probed.

Numerous screening and diagnostic measures have been developed for ASDs in recent years. These instruments include self-report, parent/teacher report, and direct observation measures. Extant diagnostic instruments have not been reliably demonstrated to be effective in making a differential diagnosis among ASDs (Campbell 2005). The current “gold standard” diagnostic protocol for ASDs consists of a parent interview, the Autism Diagnostic Observation Schedule (Lord et al. 1994), and a semistructured conversation/play-based interview, the Autism Diagnostic Observation Schedule (Lord et al. 2000). Both of these instruments are publicly available, but they require specific training to administer and score reliably. Though this combination of diagnostic measures represents best practice for diagnosing children with an ASD, it does not provide criteria for differential diagnosis among ASDs. Though great progress has been made in standardizing diagnostic approaches, this task continues to rely on the judgment of experienced clinicians.

Because ASDs are associated with difficulties in multiple domains of functioning, children thought to be at risk for ASD should be referred for a multidisciplinary assessment by an experienced team (Klin et al. 2005c). A comprehensive interdisciplinary assessment will involve a thorough developmental and health history, psychological assessment (cognitive ability, psychomotor control, adaptive function), communication assessment (receptive/expressive language, nonverbal communication, nonliteral language, pragmatics, prosody, and content, and, in young children, gaze and joint attention behaviors; Paul 2005), and a formal diagnostic evaluation, ideally using the standardized diagnostic assessments described above. An assessment of adaptive skills is also critical given the prevalence of discrepancies between intellectual level and adaptive functioning in this population (Klin et al. 2007). Consultation regarding behavioral management, motor disabilities, neurological concerns, psychopharmacology, college-readiness, or vocational training may also be indicated. As in the assessment of any childhood disorder, an accurate profile of the individual’s strengths and weaknesses will be of greater utility than simply obtaining a diagnostic label. The level of cognitive function establishes a frame of reference upon which other developmental areas (including social, communication, imagination, and adaptive skills) can be evaluated; this is critical in considering differential diagnoses, as individuals with autism display social impairments in excess of those predicted based on intellectual impairment alone.

From the perspective of the physician on a multidisciplinary team, it is important to conduct a careful medical and family history (Volkmar et al. 1999). Genetic screening for various inherited metabolic disturbances is indicated, because some inherited disorders are associated with autism (e.g., phenylketonuria). Chromosome analysis and, possibly, genetic consultation are indicated in the presence of mental retardation or signs of inherited disorders, such as fragile X syndrome. Hearing tests have often been conducted by the time a child is referred for specialized evaluation; when usual audiologic assessment procedures cannot be employed, brainstem auditory evoked response testing is indicated. Neurologic consultation should be obtained if the child has signs suggestive of overt seizure disorder or other evidence of gross neurological dysfunction or if unusual features are present (e.g., late onset). Electroencephalogram (EEG) and neuroimaging scans may be appropriate at these times (Minshew et al. 2005), but they are not recommended as standard assessment procedures. In general, a reasonable search for possible contributing factors is advisable as
indicated by history and examination, with an eye toward balancing likely yield and resource consumption.

**Epidemiology**

Initial epidemiological research on autism (Lotter 1966) suggested a prevalence rate of 4.5 in 10,000 individuals. Higher prevalence rates of broadly defined ASDs have been reported in subsequent studies with a trend toward increasing prevalence. Fombonne (2005) reviewed epidemiological studies of ASDs and found prevalence rates for autistic disorder ranging from 0.7 to 72.6 per 10,000, with the smallest sample sizes resulting in the highest estimates. Fombonne’s conservative prevalence estimate for ASDs was 36.4 per 10,000; his best estimate of the prevalence rate for ASDs was 60 per 10,000. A recent meta-analysis of prevalence studies calculated a lower rate of 20 per 10,000 for ASDs (Williams et al. 2006). A 2007 report from the Center for Disease Control reported an average of 1 in 150 children carrying a diagnosis of an ASD in the United States (Autism and Developmental Disabilities Monitoring Network Principal Investigators 2007). Though prevalence estimates have drastically increased in recent years, little evidence supports an actual change in the incidence of autism. Instead, rising prevalence rates likely reflect changes in diagnostic criteria, increased awareness of autism and ASDs, and greater service availability (Fombonne 2005). Comparability among epidemiological studies is complicated by inconsistency in diagnostic criteria used over time and across studies (Ehlers and Gillberg 1993).

In general, ASDs are more common in males than females. A ratio of approximately 4:1 has traditionally been reported (Fombonne 2005), although the recent CDC report indicated ratios ranging between 1.8 and 5.5 to 1. This ratio varies, however, as a function of intellectual functioning, with an increased ratio of boys to girls (greater than or equal to 6:0:1) in individuals with autism without cognitive impairment and a decreased ratio (as low as 1.5:1) among individuals with moderate to severe cognitive impairment. The prevalence of autism is fixed across racial and socioeconomic groups (Yeqarin-Allsopp et al. 2003).

**Comorbidity Patterns**

A variety of psychiatric conditions have been associated with autistic disorder. From a clinical standpoint, the strength of these associations and their underlying relationship is secondary to the variable presentation of the disorder, which, on the whole, renders making other psychiatric diagnoses unfruitful. Symptoms of depression and anxiety may become prominent in higher functioning adolescents, when they often venture into the social (and romantic) realm and, in so doing, become painfully aware of their limitations. Though diagnostic criteria for attention-deficit hyperactivity disorder (ADHD) specify that the symptoms do not occur in the context of a PDD, ADHD is frequently diagnosed in children with autism. A recent study (Lefler 2006) found that 55% of a sample of 109 children with autism had a significantly impairing ADHD syndrome and that 31% of the sample had symptoms that met DSM-IV-TR criteria for the disorder, with the majority falling into the category of “inattentive type.”

Research suggests correlations among autism and a number of medical conditions. Approximately 15–20% of children with autism experience comorbid epilepsy. Seizure onset appears to have two peaks of incidence, first in infancy, and then in adolescence (Volkmar and Nelson 1990, see Figure 45–2). Tuberous sclerosis, an autosomal dominant disorder characterized by benign tumors (hamartomas) in various organ systems, is associated with a range of phenotypes including mental retardation and seizure disorder. Between 20 and 50% of children with tuberous sclerosis meet diagnostic criteria for autism; the frequency of tuberous sclerosis among individuals with autism is much greater than in the typical population (Rutter 2005). These children are also more likely to suffer from epilepsy. It is not yet known whether the association between autism and tuberous sclerosis is mediated by epilepsy, the presence of localized brain lesions, or direct genetic effects. Between 15 and 25% of children with fragile X syndrome, a condition with a clear genetic basis, meet diagnostic criteria for autism. Fragile X is characterized by behavioral difficulties including attention problems, impulsivity, and anxiety. The defect has been identified as a triplet repeat of cytosine–guanine–guanine on the X-chromosome, which may amplify in successive generations. The condition is associated with a characteristic facial dysmorphism, enlarged testicles, and mental retardation. The vast majority of children with fragile X exhibit some behaviors typically attributed to autism, including social withdrawal and stereotypes; however, the pathophysiological relationship between the genetic abnormality of fragile X and autistic behaviors has yet to be clarified. Associations between autism and several other disorders, including phenylketonuria, neurofibromatosis, and congenital rubella have also been reported, but such relationships have not been conclusively demonstrated (Fombonne 2005). As an example, the “autistic-like” features of congenital rubella diminish with time, but the diagnostic process is confounded by persisting sensory deficits and mental retardation.

Figure 45–2. Rates of epilepsy (recurrent seizures) in two samples of individuals with autism/PDD (Volkmar and Nelson (1990, Deykin and MacMahon 1979) and a normative British sample (Cooper 1965). (Source: Data from Volkmar and Nelson [1990].)
symptoms as a generic stressor that can exacerbate existing symptomatology in individuals who cannot otherwise communicate their distress.

In summary, although early reports suggested that nearly half of the cases of autism were associated with a specific medical conditions (Gillberg 1992), recent, more stringent data suggest that this rate may actually be closer to 5% (Fombonne 2005).

Course
The heterogeneity of autism is particularly evident in the diversity of clinical courses it can follow. No factor has yet been identified to distinguish these children from typically developing children in the first months of life. In a retrospective study of video footage, children younger than 6 months who developed autism were less likely than their peers to focus on social stimuli (Maestro et al. 2002). This phenomenon, revealed by careful scrutiny of home video, is rarely perceived by parents or professionals at the time. By 24 months, however, 90% of parents of children with autism express concern, for reasons including delayed speech, irritability, and passivity (de Giacomo and Fombonne 1998). Given that most of the behaviors used to diagnose autism (e.g., language, intentional prosocial behaviors) have not emerged in infancy, it is quite possible that true age of onset differs from the age at which the symptoms become recognizable. Figure 45–3 illustrates reported age of onset from the DSM-IV field trial. By definition, the onset of autism is prior to age 3, but greater awareness and better screening and diagnostic instruments have facilitated early identification of the condition (Coonrod and Stone 2005, Lord and Corsello 2005). The most common first sign is a failure to develop language. Some parents may be concerned that the child is deaf, while others note that their child responds too dramatically to ambient noise. Occasionally, parents report that their child was passive, essentially “too good.” This passivity is usually accompanied by a lack of interest in social interaction or failure to display characteristic enthusiasm for looking at faces. By school age, many children with autism become more responsive socially, develop some response to joint attention (e.g., become able to follow a point), and, in some cases, become more socially drawn to familiar people (Loveland and Tunali-Kotoski 2005). Basic language skills and simple gestures may improve considerably, although other skills may remain deviant. Self-stimulatory and other problematic behaviors, such as self-abuse, can become more common and more difficult to manage as children with autism age.

A proportion of children who are ultimately diagnosed with autism are reported to have experienced normal development followed by a pronounced regression during which acquired developmental abilities were lost. Typically, language skills are reported to be lost. For example, a vocabulary of several words may suddenly disappear, sometimes permanently. The majority of regressions are reported in children aged between 18 and 24 months. Estimates of the prevalence of regression in this population have a broad range, from 15 to over 50%, but larger studies have tended toward lower estimates. Children who are reported to have experienced a regression tend to have worse outcomes than their nonregressive counterparts in the domains of receptive and expressive language, play activities, and cognitive ability (Bernabei et al. 2007). Assessment of regression in autism is complicated by limitations of retrospective parent report. Several studies using home videos or methods of inquiry designed to improve recollection by providing temporal cues and comparing recollections with an objective developmental metric suggest that many, if not most, children experiencing regressive autism actually displayed indicators of aberrant development prior to the reported regression.

A wide range of outcomes are observed in children with autism. Some children, for example, never develop speech, whereas a small minority are able to live independently. The majority of children with autism show improved social relatedness, communication, and adaptive skills as they age. Several prognostic predictors have been identified, including the presence of communicative speech, nonverbal intellectual level, and response to educational interventions. The majority of children remain socially isolated, even as they enter the school environment. For example, their interactions may be restricted to circumscribed activities, such as “tickling” games, and when left alone they will fail to initiate social interaction, focusing instead on self-directed, solitary activities. However, significant gains are often made in the social domain and in communication during the early school years; particularly when a structured and intensive program is being followed. Adolescence often is associated with a relative social decline, as the complexity of normal interactions increases exponentially. Although outcome appears to be improving, many adults with autism remain significantly impaired (Shea and Mesibov 2005). Those who are able to achieve personal and occupational self-sufficiency still exhibit residual difficulties in interpersonal interaction. In a recent study in the United Kingdom, the majority of individuals with autism continued to require extensive support in adulthood and were unable to live independently (Howlin et al. 2004). On the basis of standardized cognitive, language and attainment tests and information on social, communication and behavioral problems, many individuals experience what can be considered suboptimal outcomes. Despite historically poor prognosis, the recent development of early screening techniques coupled with refined interventions focused on realistic life skills is significantly improving the prognosis for individuals with autism. Social and adaptive abilities, along with level of language skills

Figure 45–3  Age of onset in autism (DSM-IV field trial).  
(Source: Reprinted, with permission, from Volkmar and Klin [2005].)
and nonverbal intelligence, are important predictors of independence and long-term diagnosis (Howlin 2005). Early detection and intervention are increasing the proportion of adults who can attain self-sufficiency and independent function. Indeed, studies conducted in the past 20 years demonstrate increased proportion of individuals with better outcomes and decreased proportion of those experiencing the poorest outcomes (e.g., institutional placement; Howlin 2005).

**Differential Diagnosis**

Autism must be differentiated from other PDDs, from other developmental disorders (e.g., mental retardation and language disorders), and from sensory impairments, particularly deafness. Both history and current examination are helpful in distinguishing autism from other disorders in the PDD class. In autism, the onset is most often progressive and beginning well before the third birthday, compared to the regressive patterns of onset noted in RD (normal development for 6 months followed by physical changes and degeneration of function) and CDD (normal development followed by deterioration of function after a child’s second birthday). As described in greater detail in the section on AD, confusion still surrounds discriminant validity of AD and high-functioning autism. According to current DSM-IV-TR criteria, a diagnosis of autism takes precedence over a diagnosis of AD. The early preservation of language skills in AD and the later age at which parents become concerned may be helpful diagnostic features. In higher functioning individuals with autism there is sometimes trouble distinguishing autism from the personality disorders that involve social isolation, for example, schizoid personality disorder. Table 45–1 lists differential features of autism and the other PDDs.

Severe autism can be difficult to differentiate from mental retardation. Mental retardation often coexists with autism, and the frequency of autistic-like symptoms increases with more severe retardation (Wing and Gould 1979b). Differential diagnosis focuses on specifying a social deficit greater than that predicted by cognitive impairment or developmental delay. In mental retardation, social skills can be usually expected to be commensurate with abilities in the areas of cognition and communication. The diagnostic discrimination is more complicated in persons with severe and profound retardation. In these individuals, the presence of motor stereotypes is common; these “autistic-like behaviors” often confuse diagnosticians, who mistakenly assume them to be defining characteristics of autism.

In suspected regressive autism, other disorders, including selective mutism, RD, CDD, language disorder, schizophrenia, and degenerative CNS disorders are important diagnostic considerations. Typically, children who have experienced severe neglect exhibit delayed or deviant social skills. In these cases, other features of autism are not present and the social deficits are likely to remit with appropriate care. In childhood onset schizophrenia there usually has been a long period (many years) of normal development prior to the onset of the psychotic symptoms that characterize the disorder. In some instances, the diagnosis can only be clarified with certainty over time.

Differences in Developmental, Gender, and Cultural Presentations

The majority of studies do not support Kanner’s initial impression that autism is overrepresented in children from upper socioeconomic groups. Educated parents with financial resources may be more likely to seek and obtain referrals for evaluation, and thus may be overrepresented in clinical samples. Current efforts made by governmental organizations and private interest groups to increase awareness of autism are intended to increase access to diagnostic and intervention services for children from diverse socioeconomic backgrounds.

Etiology and Pathophysiology

Genetic Factors

Autism is currently considered one of the most heritable of childhood disorders. Twin studies show increased concordance rates among monozygotic twin (60–92%) compared to dizygotic twins (0–10%) (Bailey et al. 1995). Family studies have demonstrated a rate of recurrence in siblings of approximately 5–10% (Jones and Szatmari 1988, Ritvo et al. 1989), a dramatic increase relative to the general population. Even unaffected siblings are at increased risk for various developmental difficulties; the occurrence of isolated symptoms in the absence of the complete syndrome is called the broader phenotype of autism. Research suggests that heritability is complex, involving multiple interacting genes (Risch et al. 1999). Numerous genetic studies have revealed several possible chromosomal regions involved in autism, including 2q, 7q, and 17q (Freitag 2007). A recent collaborative study implicated regions on chromosome 11 (Szatmari et al. 2007).

Neurobiological Factors

Although neurobiological factors are recognized as important in the pathogenesis of autism, neither specific biological markers nor pathogenic mechanisms have been identified. A variety of EEG abnormalities may be seen in autism, with incidence of EEG abnormalities in autism (in the absence of a clinical seizure disorder) ranging from 10 to 83% (Minshew et al. 2005). The incidence of abnormal EEGs is significantly higher in mentally retarded autistic individuals. Studies on auditory brainstem evoked potentials in autism indicate normal functioning of auditory brainstem pathways. The most robust neuroanatomical findings in autism, and in ASDs more generally, are of increased brain volume, especially with respect to temporal lobe white matter; current evidence suggests normal brain size at birth followed by overgrowth during the second year of life (Hazlett et al. 2005, Courchesne et al. 2001). Neuroanatomical differences have also focused on reduced size of the corpus callosum (Minshew et al. 2005), FMRI and event-related potential studies of hemodynamic and electrophysiological brain responses have detected abnormalities in brain activity associated with face processing mechanisms in the inferotemporal cortex (Dawson et al. 2005, Schultz 2005). An emerging body of research suggests problems with functional connectivity among separate brain regions in ASDs (Just et al. 2004) and atypical function of the motor mirror neuron system. Autopsy studies of a small number of autistic individuals have failed to reveal gross brain abnormalities. However, microscopic analysis has revealed reduced neuronal size and increased cell packing density in the hippocampus, amygdala, fornix, hypothalamic body, anterior cingulate cortex, and septum. Furthermore, decreased numbers of Purkinje cells and granule cells in the neocerebellar cortex have been described (Minshew et al. 2005). Neurochemical studies of ASDs have also produced inconsistent results. The most robust finding is elevated blood serotonin levels, but other studies have reported atypicalities in peptide excretion, neuroendocrine/HPA function, amino acid levels, uric acid excretion, and central cholinergic and gabaergic receptors (Anderson and Hoshino 2005).

Psychological Factors

Several influential cognitive theories of the social dysfunction in autism have been proposed. One hypothesis posits that there is a lack of a central drive for coherence, with the consequent focus on dissociated fragments rather than integrated “wholes,” leading to a fragmentary and overly concrete experience of the world. Another hypothesis posits deficits in “executive functioning,” that is, in the capacity to abstract rules, inhibit irrelevant responses, shift attention, and, generally speaking, to “multitask.” This hypothesis lacks specificity to autism since a range of developmentally psychiatric conditions share such deficits. Another hypothesis posits that autism is caused by an inability to attribute mental states to others. Without such a “theory of mind,” individuals with autism are presumed to be unable to infer the thoughts and motivations of others. This impairs their ability to predict the behavior of others and to formulate an appropriate response. The theory argues that this results in the observed lack of reciprocity in communication and social contact. Although the topic of much research, this hypothesis neither accounts for the very early social abnormalities in autism nor is specific to autism.

Social/Environmental Factors

For some time during the 1950s and 1960s, autism was assumed to occur secondary to poor parenting. Subsequent evidence has demonstrated that this is not the case. Several studies have shown increased rates of early medical complications in children with autism, reflecting the operation of genetic, as well as perinatal, factors. The genetic predisposition to autism may interact with perinatal factors in producing the syndrome. Some researchers have examined the role of immunological factors in autism. There has been a suggestion that maternal antibodies directed against the fetus may be produced in utero. There also have been reports of autism associated with viral infections. Though numerous environmental factors have been postulated to interact with genes to play an etiologic role in ASDs, research has not borne out consistent correlations (Wing and Potter 2002). Falling in this category are various hypotheses regarding factors contained in vaccines, such as mercury-derived preservatives and the weakened viruses themselves; though these continue to receive extensive attention in both research publications and the popular press, large studies to date have not supported a causal, or even correlative, relationship between vaccines and autism.
Treatment

Treatment Goals
No curative treatment for autistic disorder is known, and a definitive intervention does not exist for any of the core features of the disorder. Several elements have been identified by the National Research Council (2001) as common among the most effective nonpharmacological interventions: implementation in early childhood (the earlier, the better), structure, frequency, and intensity. For individuals with autism, as any child with special needs, treatment should focus on making academic content and real-life skills accessible. Given the social and communicative vulnerabilities that characterize autism, treatment should also focus on the development of age-appropriate social and communicative abilities, aiming to teach through explicit instruction the skills that are not naturally acquired during development. Recommended interventions focus on (a) devising strategies to utilize strengths (e.g., cognitive or memory skills) to compensate for areas of difficulty, (b) modifying environments to provide optimal support for learning and socialization, and (c) minimizing disruptive behaviors. Intervention programs should be tailored to the individual needs of the child, based on a thorough multidisciplinary assessment as described above. Nearly all intervention programs will include acquisition of basic social and communication skills (especially pragmatic communication), adaptive functioning, and, depending on what is developmentally appropriate, academic or vocational skills (Attwood 2000, Howlin 1999, Myles and Simpson 1997, Ozonoff et al. 2002). Intervention must also incorporate techniques to encourage generalization of acquired skills beyond the context of instruction. Appropriate intensive education should also provide support and training for parents.

Somatic Treatments

Psychopharmacology
The decision to medicate a child with autism is a difficult one as no proscribed treatment regimen comprehensively addresses the symptoms of autism. In general, drugs can be used to treat associated features of autism, but none exist to address the primary social dysfunction (though it is hoped that amelioration of behaviors that interfere with learning and social interaction can yield social benefits). Furthermore, all effective drugs carry notable side effects. Various classes of pharmacological agents have been used to target the symptoms associated with autism with mixed results. Prior to initiating drug treatment, a thorough physical examination should be conducted, including baseline laboratory studies (tests of liver and renal function, ECG, urinalysis, and blood count). Goals for treatment should be clearly defined, and data to monitor progress aggressively sought. Valuable information can come from the staff of the child’s educational and behavioral programs, and it may be appropriate to recruit these staff to collect behavioral data. When doing so, data should be collected over a period of time during a subportion of which the drug is introduced, effectively “blinding” the data collectors to reduce reporting bias.

Atypical antipsychotics, a class of medicines used traditionally for the treatment of psychotic disorders, have been used to treat disruptive behaviors in autism. A large multisite, placebo controlled study examined the efficacy of the antipsychotic risperidone for the treatment of aggression, tantrums, and self-injury in children with ASDs with compelling improvements in these target symptoms (McCracken et al. 2002). Furthermore, modest improvements in hyperactivity, repetitive behavior, socialization, communication, and daily living skills were also noted during this trial. In 2006, the Food and Drug Administration approved risperidone to treat aggression, tantrums and self-injury in children with autism between the ages of 5 and 16; this was the first approved on-label application for a drug to treat autism. Although risperidone is now considered the standard for this use, other equally potent members of the atypical antipsychotic class might also be effective, varying more in side effect profile than in efficacy. The side effects of the atypical antipsychotics, however, can be significant, thus they must be used carefully and toward an explicit and specific goal.

The selective serotonin reuptake inhibitors (SSRIs), developed for the treatment of depression, may ameliorate several groups of symptoms in the population with autism, in particular repetitive behaviors and anxiety. Although these drugs are usually well tolerated, concerns about potential for akathisia, behavioral activation, and agitation suggest that they must be prescribed judiciously. A recent meta-analysis highlighted these concerns and called for larger randomized control trials (Kolevzon et al. 2006).

Several other drug classes have been used in this population, with mixed results. The antiepileptics, a class of drugs also used for their ability to stabilize mood, have been used extensively in individuals with autism for the treatment of seizures. Research examining their effectiveness in treating mood lability, aggression, and repetitive behaviors in this group has shown inconsistent effectiveness. Stimulants are effective for the treatment of ADHD in typically developing children, and some studies have shown them to be effective for the treatment of similar symptoms in the autism population. However, reports of exacerbation of stereotypies and worsened social withdrawal have also been described. Glutamatergic agents, such as d-cycloserine, show some promise of effectiveness, pending additional research (King 2006). Others, such as secretin, although originally met with great enthusiasm after anecdotal reports of dramatic recoveries, have failed to show results under systematic study. Various chelating agents, used pursuant to controversial theories of mercury playing a causal role in development of the disorder, have failed to show effectiveness, but have been implicated in adverse outcomes (Brown et al. 2006). Advances in the understanding of the brain mechanisms underlying the symptoms of autism are constantly being made in multiple disciplines, including genetics, neurobiology, and neuroimaging. This information, it is hoped, will lead to pharmacological interventions that more specifically target the mechanisms underlying autistic symptomatology.

Complementary and Alternative Therapies
A variety of theories of both the etiology and pathophysiology of autism have generated an array of unproven treatments. Although many of these therapies are benign, others, such as behavior modification by electric shock, are potentially harmful and raise important questions about the limits of intervention. Still others have been examined...
with no demonstrated efficacy, such as modifications in diet. Information about these treatments is often communicated both by word of mouth and the Internet; published studies consist primarily of case reports. Many times, enthusiasm for alternative therapies precedes adequate investigation of the approach.

A particular concern is that complementary and alternative medicine (CAM) may have a decisive effect on the relationship between mainstream practitioners and parents. Wong and Smith (2006) described several reasons cited by parents for not disclosing the use of CAM to their child’s physician. Chief among these was “physicians’ lack of knowledge about CAM.” Another significant factor was anticipated disapproval. Thus, the mainstream is charged with maintaining a clearance-house on these topics, and individual practitioners working with autism must keep abreast of the information and maintain nonjudgmental, working relationships with parents. In advising parents of children with autism, the first concern for alternative therapies should be the child’s safety. Then a consideration of the cost and the time involved in the therapy is appropriate to ensure that there is no interference with more established forms of therapy underway.

Psychosocial Treatments

Education
Children with autism require intensive, highly structured special education from educators specifically trained to work with individuals on the autism spectrum. Early, continuous intervention is highly desirable and has measurable effects on later intellectual and communicative functioning. Educational interventions are best provided over a full day of school on a year-round basis, as breaks are poorly tolerated and can result in loss of skills. Classroom settings with a low student to teacher ratio (ideally individualized instruction) are ideal. For the most impaired children, goals should include teaching the child (1) to tolerate individual adult guidance in performing tasks, or acquiring “learning to learn skills,” (2) to follow a daily routine, (3) to develop functional communication, and (4) to move from concrete associations to understanding concepts. Learning environments should minimize distractions; individual workstations and physical prompting may be necessary. The use of highly predictable and consistent routines supports the child’s own internal sense of order, scheduling, and organization of experiences to promote learning. Children with autism often learn skills in response to very concrete instruction and limited to specific settings. Therefore, it is important to ensure that the child uses acquired skills spontaneously and can generalize these skills to other settings. Children with autism may acquire a considerable vocabulary and yet fail to use these words for effective communication. Therefore, any efforts toward enhancing language acquisition should focus on the communicative function of language. For example, vocabulary expansion should focus on words that are relevant to meeting a child’s basic needs. Children who do not vocalize should be engaged in programs focused on alternative forms of communication, such as written signs, communication boards, and other forms of augmentative communication. The utilization of these alternative forms of communication should not derail development of vocal communication in children for whom this represents a realistic goal.

For older or intellectually able children, educational program should focus on social and communication skills training. The skills to navigate challenging situations should be rehearsed and scripted; concrete social and communicative skills (e.g., eye gaze, voice modulation, gesture, posture, proximity, greeting behaviors, conversation, and social mores) should be taught in a very explicit fashion. This education should move from static concrete representations of social interaction to increasingly dynamic, realistic contexts. Correspondingly, the teaching environment for social skills therapy may alternate between small group instruction (allowing for teaching and practice with adult facilitation and feedback) to naturalistic settings (starting with adult facilitation and fading support over time). Successful techniques used for this purpose include modeling of behaviors by an instructor, self-observation, role-playing, and the use of individualized social stories.

Behavior Therapy

Even among the lowest functioning children on the autism spectrum, behavior modification techniques have been successfully employed to establish desired behaviors and reduce problem behaviors. Behavior modification may reinforce appropriate behaviors and lessen inappropriate ones, facilitating involvement in educational programming (Lovaas 1987). Most educational programs for children with autism utilize behavioral management techniques, although they vary in the degree to which these are integrated into the comprehensive educational program. Behavior therapy is particularly useful in the management of disruptive behaviors, including difficulties in attention and compliance, tantrums and self-injurious behavior. The first step entails functional behavior analysis to identify environmental antecedents and the purposes these behaviors serve for a child. Next, behavioral techniques, such as shaping or extinction, are used to decrease effectiveness of maladaptive behaviors and promote a desired alternative behavior. Behavioral principles are also utilized for learning, including the promotion of early cognitive skills such as categorization and elicitation of vocalization and speech. An appropriate behavior curriculum should place special emphasis on generalization and self-initiated skills. It is also important to ensure that the child would not benefit from more typical teaching modalities, as behavior therapy can be resource intensive.

Psychotherapy

As a biological etiology for autism has been recognized, psychodynamic and unstructured play therapies have been rendered less focal in the treatment of children with autism. Individual psychotherapy may be appropriate for higher functioning individuals presenting with anxiety and depressive symptoms. In these cases, psychotherapy should focus on explicit problem-solving skills rather than undirected, insight-oriented approaches. Cognitive–behavioral therapy tailored specifically to individual profiles of strengths and weaknesses may be helpful with adolescents and adults. Organized social interactions (social groups) may be extremely effective, providing opportunities to learn and practice social skills with peers.
Asperger’s Disorder

Definition and Diagnostic Features
AD is currently differentiated from other ASDs by the preservation of linguistic and cognitive abilities despite profound social disability and circumscribed interests (American Psychiatric Association 2000). AD is named after an Austrian pediatrician, Hans Asperger. In 1944, at approximately the same time when Leo Kanner described children with “autism” in the United States, Asperger described a group of school-aged boys with intact cognitive and language skills but difficulties with social interaction (Asperger 1944). He called the disorder “autistic personality disorder.” Asperger noted poor social integration, reduced nonverbal communication, idiosyncratic verbiage, strong (and often unusual) areas of interest, limited empathy, clumsiness, and behavior problems. Asperger suggested that these difficulties did not emerge before 3 years of age, and he commented on the apparent heritability of the disorder.

In 1981, Lorna Wing translated Asperger’s manuscript into English, introducing the diagnostic concept into American psychiatry and elaborating upon it (Wing 1981). Wing modified Asperger’s original characterization by describing symptoms of the disorder evident during the first 24 months of life including disinterest in others, decreased prelinguistic verbalizations, reduced sharing of interests, stereotypic speech, and limitations in imaginative play. Subsequent to Wing’s publication, diagnostic criteria for AD were incorporated into the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 1994).

Clinicians and researchers continue to struggle with the most appropriate diagnostic conceptualization of AD, especially in terms of distinguishing it from other high-functioning ASDs. Current diagnostic criteria in the DSM-IV-TR (see DSM-IV-TR criteria for Asperger’s Disorder) distinguish AD from autism based on the absence of language delays and the preservation of cognitive ability and daily living skills (American Psychiatric Association 2000). Specific diagnostic criteria require that an individual demonstrate two symptoms within the social domain and at least one symptom from the domain of restricted, repetitive, and stereotyped behaviors. The diagnosis of AD also requires that the social disturbance be significant enough to detrimentally impact functioning in terms of self-sufficiency, employment, or other important areas of functioning.

One of the most striking clinical features of AD is the focused pursuit of specific areas of interest. This is typically evident by grade school, when many children with AD have accumulated volumes of information about a narrow area of expertise. The particular topic of interest is not always consistent across development. The content of circumscribed interests may be unusual or developmentally inappropriate (e.g., interest in public transit or electronic circuitry), but some interests are atypical only in degree (e.g., interest in sea animals). The circumscribed interests characteristic of AD possess an obsessive and intrusive quality, often in the absence of a practical, contextual understanding of the topic. For example, a child might be interested in memorizing the model numbers of vacuum cleaners without any interest in learning to use them.

These circumscribed interests complicate the social interactions of people with AD. Although some children with

---

**DSM-IV-TR Criteria for Asperger’s Disorder**

A. Qualitative impairment in social interaction, as manifested by at least two of the following:

1. marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction,
2. failure to develop peer relationships appropriate to developmental level,
3. a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing or pointing out objects of interest to other people)
4. lack of social or emotional reciprocity

B. Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following

1. delay in or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime)
2. in individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
3. stereotyped and repetitive use of language or idiosyncratic language
4. lack of varied spontaneous make-believe play or social imitative play appropriate to developmental level

C. The disturbance causes clinically significant impairment in social, occupational, or other important areas of functioning

D. There is no clinically significant general delay in language (e.g., single words used by age 2 years, communicative phrases used by age 3 years).

E. There is no clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment in childhood.

F. Criteria are not met for another specific Pervasive Developmental Disorder or Schizophrenia.
AD display disinterest in social interaction or engagement with peers, many actively pursue social contact. However, long-winded, fact-based monologs, characteristic of these children, often alienate them from peers. Unfortunately, for many children with AD, a desire for social companionship evident in early childhood may diminish over time after repeated failed social encounters. Deficits in empathizing have been reported to be more subtle than in individuals with autism (Kaland et al. 2002). Intact cognitive skills often allow children with AD to approximate typical social skills in clinical contexts or those in which expectations are clear; these skills look worse in the context of rapid, fluid social interactions (Klin et al. 2002a). Children with AD may distill social interactions to determine rules of behavior and guidelines for social interaction. Subsequent application of these rules may lead to awkward social behaviors, such as inappropriate, sustained eye contact or theatrical use of gestures, conveying, at best, social naïveté to their peers (Klin et al. 2005a).

Preserved linguistic facility in AD only requires that children with AD acquire language “on time.” Language acquisition and use tends to be atypical in several respects. Children with AD may possess a precocious vocabulary while still quite young. Speech quality is often pedantic, and children with AD may speak intrusively and at great length about their interests. The comments of a conversational partner may be ignored, talked over, or nominally regarded. The volume of speech is often loud or inappropriately modulated. Tone is frequently observed to be nasal with poor prosody and limited use of affective inflection (Ghaziuddin and Gerstein 1996). A failure to appreciate the listener’s perspective and a consequent omission of background information and transitional phrases may result in speech patterns that appear loose or tangential.

Clumsiness has been noted as a feature of the disorder since Asperger’s initial account. Children with AD often appear to move awkwardly, and they often have difficulty accomplishing childhood tasks that require motor dexterity. Research has documented unusual gait patterns, odd posture, poor handwriting, problems with visual motor integration, and proprioception (Tantam 1988, Gillberg 1990, Weimer et al. 2001). Poor motor coordination skills have not been demonstrated to be a unique feature of AD versus other high-functioning ASDs (Smith 2000, Green et al. 2002).

Individuals with AD often exhibit a distinctive neuropsychological profile. Klin et al. (1995) compared individuals with AD to those with high-functioning autism (HFA) on a variety of neuropsychological measures. Individuals with AD exhibited deficits in fine and gross motor skills, visual motor integration, visual-spatial perception, nonverbal concept formation, and visual memory despite normal articulation, verbal output, auditory perception, vocabulary, and verbal memory. Other studies have reported that AD is associated with stronger verbal abilities relative to performance abilities, with particular weakness in visual-spatial organization and graphomotor skills (Ghaziuddin and Mountain-Kimchi 2004, Ehlers 1997). This neuropsychological profile is often referred to as nonverbal learning disability (NLD; Rourke 1989). In contrast, individuals with other high-functioning ASDs typically demonstrate the reverse pattern, that is, lower scores on measures of verbal functioning (Reitzel and Szatmari 2003). Some researchers have argued that individuals with AD possess greater broad cognitive ability than individuals with HFA, irrespective of verbal ability or verbal-nonverbal discrepancy (Miller and Ozonoff 2000). Understanding of the utility of neuropsychological profile as a distinguishing feature of AD is complicated by use of heterogeneous diagnostic schemes in research studies (Klin et al. 2005b).

Clinical Vignette 2: Asperger’s Disorder

Adam was the third of three children born to a social worker and an office manager. No medical problems were reported during pregnancy or birth, and his medical and family history was unremarkable. His pediatrician expressed mild concern during the first 24 months of his life because his motor milestones (e.g., sitting up, walking) consistently fell at the late end of normal limits. His language development was precocious; he had amassed a for-
Assessment
Assessment for AD is as described above for autism. Though diagnostic screeners have been developed to identify individuals with AD, none have yet been shown to reliably and accurately differentiate individuals with AD from those with other ASDs, especially HFA (Lord and Corsello 2005).

Epidemiology
Fombonne and Tidmarsh (2003) reviewed epidemiological studies of AD and found prevalence rates ranging from 0.3 to 48.4 per 10,000; the authors suggested a working prevalence rate of 2.6 per 10,000 for AD. The condition is more prevalent in males than females, with a reported ratio of 9 to 1.

Comorbidity Patterns
The most common disorders co-occurring with AD are depression and anxiety. Research estimates of comorbid anxiety and/or depression in individuals with AD are as high as 65%, and some researchers have suggested that these elevated rates distinguish AD from HFA (Ghaziuddin et al. 1998, 2002, Green et al. 2000). Other data suggest, however, that individuals with AD and HFA are equally at risk for problems with anxiety and depression (Kim et al. 2000). Anxiety in AD may stem from violations of their rigid routines and rituals or social anxiety, that is, a preoccupation with failing during social encounters. Serious depressive symptoms may also be experienced, often in the context of social failure and loneliness. Hyperactivity and inattention are common among children with AD (Eisenmayer et al. 1996, Schatz et al. 2002), and many children with the disorder are often initially misdiagnosed with attention-deficit/hyperactivity disorder. Some studies have associated AD with Tourette's syndrome (Kerbeshian and Burd 1986, Littlejohns et al. 1990, Marriage et al. 1993), obsessive–compulsive disorder (Thomsen 1994), and psychotic conditions (Gillberg 1985). Researchers have investigated and rejected the notion that preserved intellectual function coupled with limited empathy may predispose individuals with AD to violent or criminal behavior (Everall and LeCouteur 1990, Ghaziuddin et al. 1991). As described above, the unique neuropsychological profile of nonverbal learning disability has also been associated with AD (Stein et al. 2004).

Course
Because, by definition, children with AD develop language and self-help skills in a timely manner, these red flags are not evident in early childhood. Therefore, these children are not typically identified until later in development. Furthermore, the more subtle impairments associated with AD, such as impairments in social reciprocity and special interests, may not be evident until a child attains the developmental level of a typical grade school student. Research indicates that diagnosis of AD is most commonly made after 4 years of age (Szatmari et al. 2003) and often as late as 11 years (Howlin and Asgharian 1999, Gillberg and Cederlund 2005). Though research in the early detection and diagnostic stability of AD is complicated by inconsistencies in diagnostic systems, a recent study suggests that diagnosis of AD cannot be rendered with reliability prior to age 4 (McConachie et al. 2005).

Despite later diagnosis, parents of children with AD retrospectively report concerns about their child’s behavior, social motivation, language, play, or insistence upon sameness before age 3 (Gilchrist et al. 2001) and as early as 20 months of age (Chakrabarti and Fombonne 2005). In contrast to other ASDs, the disabilities associated with AD may not be readily evident in the context of social interactions with adults, who are often charmed by what they perceive as precocity. Subtle indicators in early childhood may be approaching adults for instrumental rather than social reasons. For example, children with AD might use language or gesture to engage adults for making requests (e.g., “That toy is out of reach”) instead of sharing interests (e.g., “That toy is interesting to me”). By preschool age, strong interests in a particular subject matter are commonly evident. The social disability associated with AD is often first noticed when children encounter public settings with peers, such as daycare or preschool. These children may actively avoid interactions with other children or make social overtures in atypical ways (e.g., by abruptly introducing a fact about a special interest). Another early indicator of AD may be behavioral rigidity. This trait can manifest as ritualizing daily activities, such as dressing in a particular sequence, or stringently adhering to a schedule. Rigidity can interfere with social interactions, and children with AD may become upset when other children fail to do things “right.”

Asperger’s (1944) initial description of these children predicted positive outcomes based on the presence of intact cognitive ability and the potential for the application of special skills in gainful employment. Compared to lower functioning individuals with ASD, more positive outcome can indeed be expected, especially in the domains of academics and self-help skills (Gillberg 1991). Differential outcome compared to other high-functioning ASDs is still under investigation, and some have suggested that comparable outcomes may be expected of individuals with AD and HFA (Szatmari et al. 1989). Adolescents with AD continue to have difficulty with independent self-care and organization, and they exhibit ongoing disturbances in social and romantic relationships. Studies of young adults with AD report that most remain at home despite high cognitive potential, but a minority marry and work independently (Tantam 1991).

Differential Diagnosis
The great majority of children with ASDs experience early delays and deviance in language acquisition and cognitive impairment and are thus readily distinguished from children with AD. Differential diagnosis between AD and HFA is more difficult, and research has yet to conclusively demonstrate that the two disorders are reliably distinctive. By strict diagnostic criteria, AD differs from HFA in terms of appropriate developmental attainment of language milestones. Social and communication deficits may be less severe in AD, and motor mannerisms may not be evident. In contrast, circumscribed interests are more salient and motor awkwardness is more common in AD. In DSM-IV-TR, if the child meets criteria for autism, this should take precedence over a diagnosis of AD. Given the nonspecific diagnostic criteria for PDD-NOS (described in detail in the PDD-NOS section below), the distinction between AD and PDD-NOS is less consistent. Individuals with AD tend to display more significant social impairment with less pronounced communication deficits. Children with AD also...
exhibit intense, circumscribed interests that are a focus of verbiage. Cognitively able, verbal children will often be diagnosed with PDD-NOS in lieu of AD if they fail to present with such preoccupations. Clinical reports stress circumscribed interests, verbosity, and motor clumsiness in AD versus PDD-NOS. Schizoid personality disorder shares some of the social features, but individuals with this disorder do not show the level of severity of social impairment nor the early developmental patterns characteristic of AD. For these reasons, a detailed developmental history documenting early onset and continuity of symptoms may be important in the differential diagnosis.

Etiology and Pathophysiology

Genetic Factors
Many case reports have reported AD, ASD, or autistic-like traits in family members of those with AD, particularly among fathers (Gillberg and Cederlund 2005, Ghaziuddin 2005). Klin et al. (2005b) reported rates of ASDs or subclinical autistic features (the broader autism phenotype) in parents and grandparents of probands with AD that were triple the rate found for the same relatives of probands with HFA (17% vs. 5%). Though this finding suggests that AD may have an even stronger genetic component than autism (Volkmar and Klin 2000), the preponderance of research suggests shared genetic mechanisms common to all ASDs (Frith 2004). Though no clear genetic etiology has been established for AD, some studies have reported specific genetic abnormalities in case studies of patients with AD: translocations (balanced and de novo) (chromosomes 1, 5, 11, 13, 14, 15, 17) (Anneren et al. 1995, Tentler et al. 2001, Cederlund and Gillberg 2004, Tentler et al. 2003), autosomal fragile site (Saliba and Griffiths 1990), fragile X syndrome (Bartolucci and Szatmari 1987), Fragile Y, and 21p+ (Cederlund and Gillberg 2004).

Neurobiological Factors
Several reports of medical abnormalities associated with AD have appeared, but no factors have been reliably associated with AD across studies. Wing (1981) reported a high frequency of perinatal problems (nearly half of her original sample) among individuals with AD. Other reports have associated AD with medical conditions, including aminoaciduria (Miles and Capelle 1987) and ligamentous laxity (Tantam et al. 1990). A case series by Gillberg (1989) reported high frequencies of medical anomalies common to both AD and autism, but these results have not been consistently replicated (Rutter et al. 1994). Increased rates of epilepsy have been observed among individuals with AD (Cederlund and Gillberg 2004). Anomalies have also been detected in eye movements and visual scanning in individuals with ASDs (Sweeney et al. 2004), particularly when viewing social scenes (Klin et al. 2002b), but these findings have not yet been shown to distinguish AD from other ASDs. Neurochemical research has not revealed anomalies specific to AD (Anderson and Hoshino 2005). Neuroimaging research has not revealed any common pathologies among individuals with AD, both with respect to typical individuals and in terms of differentiation among other ASDs. Berthier et al. (1990) reported MRI results indicating left frontal macrogyria and bilateral opercular polymicrogyria in patients with AD. Other studies have reported gray tissue anomalies (McAlonan et al. 2002, Kwok et al. 2004), left temporal lobe damage (Jones and Kerwin 1990), left occipital hypoperfusion (Ozbayrak et al. 1991), and dysmorphology superior to the ascending ramus of the Sylvian fissure proximal to the intersection of the middle frontal gyrus and the precentral sulcus (Volkmar et al. 1996). Functional imaging has also failed to detect reliable differences among AD and other ASDs. SPECT imaging has suggested abnormal right hemisphere functioning in AD (McKelvey et al. 1995). Other research has found dysfunction in brain regions subserving social cognition (anterior cingulate cortex, prefrontal cortex, temporoparietal junction, amygdala, and periamygdaloid cortex (Schultz and Robins 2005). Abnormal functional connectivity among brain regions has also been implicated in AD (Welchew et al. 2005).

Psychological Factors, Social/Environmental Factors
Hypothesized psychological and social factors are as described for autism.

Treatment

Treatment Goals
As with autistic disorder, no cure exists for AD. Aside from considerations relevant to linguistic capability, verbal strengths, or nonverbal vulnerabilities, comparable treatment guidelines apply to AD and other high-functioning ASDs (Mesibov 1992).

Somatic Treatments

Psychopharmacology
Medications are frequently prescribed for individuals with AD despite limited data on efficacy. As with autism, there are no medications that address the core social and communicative features of AD; thus treatment should be targeted at ameliorating symptoms and maximizing adaptive gains. In combination with behavioral interventions, they may be effective in treating the constellation of symptoms associated with AD, including anxiety, depression, inattention, and aggression. The specific classes of agents discussed in the section on autism are utilized for the same reasons in AD. It has been argued that individuals with AD may have atypical responses to medications, even when compared to other individuals with ASD (McDougle et al. 1998), but data remain inconclusive. Very few studies of pharmacological interventions for AD exist. The atypical antipsychotics risperidone and olanzapine have shown efficacy to diminish externalizing behavior (e.g., aggression and agitation) associated with AD, to improve global functional levels, and to lowering AD symptomatology (McCracken et al. 2002, Milin et al. 2006). A thorough appreciation of the wide range of symptoms manifest in AD is essential for the prescriber. Polypharmacy should be avoided when possible, and a clear notion of what is being targeted should be maintained. Information about progress should be obtained from all members of the care team, and medications that are not meeting the explicit predetermined goals should be reevaluated.
Complementary and Alternative Therapies
As with autism, a host of complementary and alternative treatments exist for AD. Limited research exists to support most of these treatments.

Psychosocial Treatments
As in autism, treatment of AD is essentially supportive and symptomatic, and, to a great extent, treatment guidelines overlap with those for individuals with HFA. No systematic research has demonstrated unique efficacy of any one intervention modality (Klin and Volkmar 2003). As children with AD are often quite verbal and perform well academically, parents often encounter resistance in seeking services. However, targeting their profound social impairments and deficient adaptive skills should indeed be incorporated into any educational intervention. Learning strategies and social mores are best taught in an explicit and rote fashion using a parts-to-whole verbal instruction approach, providing the child with explicit steps to perform effectively. Specific treatment guidelines should be developed according to the individual’s unique neuropsychological profile. The acquisition of self-sufficiency skills should be a priority, and a tendency to rely on rigid rules and routines can be exploited toward this end.

A verbal algorithm approach may be applied to social problem solving and for handling the requirements of troublesome situations that can be anticipated (e.g., encountering novelty or frustration). Specific teaching should address recognition of troublesome situations and selection of the appropriate strategy to employ. Social and communication skills are best taught by a communication specialist in the context of both individual and small group therapy. Communication therapy should include use and decoding of nonverbal behaviors, social awareness, perspective-taking skills, and interpretation of nonliteral language. Adults with AD should be trained for and placed in jobs appropriate to their social and neuropsychological characteristics (including job application and interview skills). It is preferable that employment does not entail intensive social demands, time pressure, or the need to quickly improvise or generate solutions to novel situations. Anecdotal evidence suggests that individuals with AD may benefit from participation in support groups. Opportunities for social interaction may be built around special interests (e.g., hobby groups). Supportive psychotherapy may be helpful in dealing with feelings of despondency, frustration, and anxiety; a cognitive-behavioral, problem-solving focus is likely to yield greater benefit than insight-oriented approaches.

Childhood Disintegrative Disorder

Diagnosis

Definition and Diagnostic Features
CDD is a relatively rare condition in which clinical features resembling autism develop after a period of normal development. The disorder was first described by Theodore Heller (Heller 1908), who termed the condition dementia infantilis; subsequently, it has also been referred to as disintegrative psychosis or Heller’s syndrome. Nearly 200 cases have now been reported in the literature (Volkmar et al. 2005). The DSM-IV-TR definition (see DSM-IV-TR criteria for Childhood Disintegrative Disorder) of the disorder specifies ostensibly normal development for at least the first 2 years of life followed by clinically significant loss of previously acquired skills in at least two areas (expressive or receptive language, social skills, bowel or bladder control, play, or motor skills). The individual must also exhibit qualitative impairment in social interaction, communication, and restricted, repetitive, and stereotyped patterns of interest as defined for autism. The regression in skills must occur before age 10 years. By definition the condition is not better accounted for by another PDD.

Clinical Vignette 3: Childhood Disintegrative Disorder

Ralph developed typically throughout infancy, and his developmental milestones were all on time. Shortly after his third birthday, his phrase speech diminished, and he began showing less social initiative. During the span of a few months, his speech disappeared completely. He also lost bowel control and began displaying motor stereotypes and engaging in repetitive behavior with objects. He no longer responded when his parents or siblings called his name, and he displayed enjoyment in interactions with other people only when interactions involved tickling or being spun in the air. A battery of medical tests, including MRI and clinical EEG, were administered with negative results. Ralph was enrolled in a small private school for children with autism. He developed minimal functional communication and transitioned to institutional care in adulthood.

Assessment
Assessment procedures are essentially the same as for autism except that more extensive medical evaluations are indicated to rule out other medical conditions associated with developmental deterioration, such as neurolipidosis and Addison–Schilder's disease. These include the search for inherited disorders (e.g., of metabolism) or other conditions characterized by developmental deterioration. A neurological assessment, including EEG and an MRI scan, should be obtained.

Epidemiology
Epidemiological data are limited but the disorder appears to be extremely rare, with prevalence estimates in the range of 1 in 100,000 children (Volkmar et al. 2005).

Comorbidity Patterns
In general, children with this condition have limited communication skills and severe intellectual disability. A variety of medical conditions, for example, the neurolipidoses, metachromatic leukodystrophy, Addison–Schilder's disease, and subacute sclerosing panencephalitis, can be associated with loss of developmental skills, and these would be diagnosed as comorbid if their presence is documented. Usually, however, intensive medical investigation does not reveal the presence of such conditions.

Course
Usually, the onset of CDD is between the ages of 3 and 4 years. There may be nonspecific agitation or anxiety prior to developmental deterioration; the onset may be gradual or abrupt. The loss of skills is of great concern to parents who typically seek extensive medical evaluations to determine the cause of the deterioration in the child's development. In most instances (probably about 75% of cases), after the developmental deterioration, the child's behavior stabilizes, with no further deterioration but minimal subsequent gains. In some cases, a partial recovery occurs (e.g., recovery of single word or phrase speech), and, rarely, children make a more substantive recovery. If the condition is associated with a progressive neuropathological process, deterioration can be progressive; otherwise life expectancy is normal. It appears that the outcome of the condition is worse than that for autism (Volkmar and Cohen 1989).

Differential Diagnosis
CDD may be differentiated from regressive autism based on the timing and severity of loss of skills. For a diagnosis of autism, the difficulties must be evident prior to age 3; if loss of skills occurs subsequent to the third birthday, CDD is the more appropriate diagnosis. Furthermore, in most cases of regressive autism, the child will typically not have progressed to speaking in sentences (as may be the case for children who develop CDD), and other signs of disturbance (e.g., social difficulties) are likely to be present prior to any perceived regression. Differential diagnosis from RD can be based on Rett's characteristic head growth deceleration and specific clinical features. The syndrome of acquired aphasia with epilepsy (Landau–Kleffner Syndrome) is characterized by development of an aphasia, but, unlike CDD, social interest and nonverbal communicative skills are often preserved.

Differences in Developmental, Gender, and Cultural Presentations
The condition is about five times more common in males than females. It is likely that some early reports of females actually represented misdiagnosed cases of RD.

Etiology and Pathophysiology
Various lines of evidence support the importance of neurobiological factors in the pathogenesis of CDD, though no unique etiologic or pathologic features have been revealed. Seizures are sometimes observed, and the EEG is reported to be abnormal in about half of cases.

Treatment
Treatment is as for autism with an emphasis on use of special educational and behavioral interventions to help the child reacquire lost skills and gain new abilities. Pharmacological interventions may be helpful in dealing with agitation and stereotyped mannerisms if these interfere with the child's functioning.

Rett's Disorder

Definition and Diagnostic Features
Rett's disorder (RD), also called Rett's syndrome, is a rare genetic neurodevelopmental disorder that almost invariably affects females. The disorder is characterized by a period of normal development, usually the first 6 months of life, followed by deceleration of head growth, social withdrawal, and a generalized slowing of development. A regressive phase follows, during which previously acquired receptive and expressive language skills are lost. During this period, motor skills, specifically purposeful hand skills, also regress and are replaced by characteristic hand stereotypes of hand-wringing and washing motions (Van Acker et al. 2005). This regression may take place insidiously over a prolonged course or more abruptly in the span of several days. Generally around the age of 3, this regression slows, leaving severe mental retardation and neurological deficits, including spasticity, seizures, and trouble coordinating breathing and eating (Moser et al. 2007). Improvements in social engagement are often seen during this plateau. During early puberty, there is generally further deterioration in
motor function, with progressive scoliosis and muscle wasting. Children with RD often become wheelchair bound.

Assessment
The unique natural history must be considered when evaluating suspected cases of RD and is particularly important in generating differential diagnoses. For children who meet clinical diagnostic criteria for RD (see DSM-IV-TR criteria for Rett’s Disorder), a work-up described as for autism is indicated. It is particularly important to do both a comprehensive neurological evaluation, including EEG monitoring for seizure activity, as well as molecular genetic analysis to confirm mutation in the gene associated with RD. Once a diagnosis of RD is confirmed, or when it is strongly suspected, the patient should be examined to rule out seizures, reflux disease, cardiac anomalies, and respiratory anomalies.

### DSM-IV-TR Criteria for Rett’s Disorder

A. All of the following:

1. Apparently normal prenatal and perinatal development
2. Apparently normal psychomotor development through the first 5 months after birth
3. Normal head circumference at birth

B. Onset of all of the following after the period of normal development:

1. Deceleration of head growth between ages 5 and 48 months
2. Loss of previously acquired purposeful hand skills between ages 5 and 30 months with the subsequent development of stereotyped hand movements (e.g., hand-wringing or hand washing)
3. Loss of social engagement early in the course (although often social interaction develops later)
4. Appearance of poorly coordinated gait or trunk movements
5. Severely impaired expressive and receptive language development with severe psychomotor retardation

### Epidemiology
RD occurs in less than 0.01% of live births (Van Acker et al. 2005). Varied reports of the incidence of the disorder from across the world may be attributed to diagnostic differences but highlight the fact that a diversity of racial and ethnic groups are affected. Contrasting to the male bias in affected individuals for the other PDDs, RD almost invariably affects females, reflecting the X-linked genetic basis of the disorder.

### Comorbidity Patterns
The severe neurological impact of RD leads to diverse sequelae. Thus it is difficult to untangle comorbid conditions from those that may be attributable to the primary process. The majority (60–70%) of children with the disorder experience epileptiform activity of some sort that can be difficult to distinguish clinically from stereotypes. Aside from motor difficulties with feeding, the majority of children with the syndrome also have abnormal digestive system functioning, including reflux disease and disrupted motility. As a result, these children often suffer from malnutrition and a secondary failure to thrive (Lotan and Zysman 2006).

### Course
RD is characterized by a period of normal development, followed by a progressive deterioration. The functional level of patients with the disorder is variable, with a significant number of children retaining some functional skills and approximately half retaining their ability to walk. Table 45-2 lists the clinical features of each of the stages of RD.

### Differential Diagnosis
The clinical manifestations of RD are distinct at each stage of the disorder; thus differential diagnosis will vary according to stage at presentation. Primary among these considerations at the earlier stages are other PDDs, including autism and CDD. Later in development, disorders with neurological manifestations, including, but not limited to,
encephalitis, chromosomal disorders, tuberous sclerosis, and Landau–Kleffner syndrome, must be considered.

**Etiology and Pathophysiology**

**Genetic Factors**
RD is associated with de novo mutations in the MeCP2 gene found on the X-chromosome and associated with DNA methylation and the regulation of multiple genes responsible for brain development and regulation (Amir et al. 2000). Associated downstream alterations in neuroanatomy and neurochemistry have been identified. The MeCP2 gene appears to be expressed only after neurons have reached a certain level of development corresponding to the natural history of the disorder (Shahbazian et al. 2002).

**Neurobiological Factors**
RD is accompanied by diminished brain volume and a host of neurochemical changes in the central nervous system.

Changes in the immunological system, such as autoantibodies to nerve growth factor, also occur and appear to be associated with the changes to the nervous system (Gratchev et al. 2001).

**Psychological Factors**
The social changes in RD have similarities to the core social deficits observed in autism; whether a psychological model of the social disruption in Rett’s can be derived from a model for autism remains to be explored.

**Social/Environmental Factors**
The majority of cases of Rett’s result from a known genetic mutation. As such, neither social nor environmental factors contribute significantly to the onset and course of the disorder. Several case reports have described the Rett’s phenotype subsequent to an environmental factor, but insufficient information exists to support specific associations.
Chapter 45  •  Childhood Disorders: The Pervasive Developmental Disorders

Treatment

Treatment Goals
Rett’s has no cure, nor has a definitive therapy been identified to alter its course. Thus, the current targets of treatment are symptoms and sequelae. Addressable factors can be loosely categorized into motor/neurological deficits, social communication deficits, and medical sequelae. To address the neurological changes, experts in occupational and physical therapy, orthopedics, and neurology should be utilized. The social and communication deficits require experts in speech and language, as well as child psychologists or psychiatrists experienced in the treatment of developmental disorders. A pediatrician with experience in Rett’s is recommended to coordinate both general treatment and treatment of medical complications. Given the characteristic gastrointestinal complications, a nutritionist is also recommended (Lotan and Zysman 2006).

Somatic Treatments
A variety of pharmacological therapies (dopamine agonists and antagonists, L-carnitine, tyrosine, and melatonin, among others) have been employed to target the underlying pathophysiology of RD, but no compelling effects have been recorded. The seizures associated with the syndrome should be addressed in the same way that they are in any child with a seizure disorder. A variety of antiepileptic agents are effective. Gastrointestinal symptoms should be addressed on a case-by-case basis, and both antireflux and motility enhancing agents may be indicated. Because children with RD are generally small in stature and vulnerable to malnutrition, great care must be taken to plan diets appropriately. A high calorie diet rich in calcium is essential. No current treatment exists to address the basic neurological insults in RD; however, given the defined genetic basis of the disorder, current research is investigating whether the abnormal gene could be swapped or repaired in vivo. Recent results from a mouse model of the disorder raise the possibility that the neurological defects that accompany the disorder may be reversible with the development of successful gene therapy (Guy et al. 2007).

Psychosocial Treatments
Raising a child with Rett’s places considerable strain on a family, and psychosocial support for the family is an important aspect of treatment. This includes helping to ensure an appropriate educational setting and plan, as well as assistance accessing resources and services. The challenge that these children present to the clinician is also considerable, demanding vigilance, patience, and above all compassion.

Pervasive Developmental Disorder—Not Otherwise Specified

Diagnosis
PDD-NOS, or atypical autism, refers to a residual category. As such, rather than being characterized by a set of distinct features, the definition of this category reflects the absence of defining features required for other PDDs. The diagnosis denotes a subthreshold form of autism, or a manifestation of autism that is atypical in terms of onset patterns or symptomatology. Diagnosis requires that the child exhibit autistic-like social difficulty along with impairment in either communication or restricted/repetitive interests or behaviors. Thus, PDD-NOS describes a diverse group of children who do not meet strict criteria for autism or another PDD despite social and communicative and/or behavioral deficits. The limited available evidence suggests that children with PDD-NOS may be diagnosed later than children with autism and intellectual deficits may be less prevalent (Dahl et al. 1986). Persons with PDD-NOS may experience better outcomes because of milder symptomatology, stronger social motivation, or preserved communicative or cognitive abilities (Towbin 2005). Though patterns of regularly co-occurring phenotypes are likely to yield subgroups in this diagnostic category in the future, current research has not refined this undifferentiated diagnostic class.

Clinical Vignette 5: PDD-NOS

Jonathan was an only child born to an engineer and an office manager, at 29 and 25 years of age, respectively. He experienced difficulties with breastfeeding in early infancy, failing to latch appropriately until approximately 6 weeks. He eventually became proficient at breastfeeding, but, when transitioned to solid foods, displayed extreme pickiness in terms of the textures he would consume. Parent reports indicate that he was a pleasant baby who was easily soothed, but he failed to develop a regular sleep schedule until his second year of life. Jonathan met all motor and language milestones, though pediatric records indicate low tone throughout infancy. Parents report reduced social interest throughout infancy, specifically less looking at people than expected and infrequent smiling at other people. During the second year of life, Jonathan’s pediatrician referred his family for an evaluation, and Jonathan began receiving early intervention to address social development. At an evaluation at age 48 months, Jonathan presented with intellectual abilities comparable to same age peers and slightly delayed language skills on standardized speech and language assessment instruments. He displayed an interest in particular movies, and, when left to his own devices, often recited lines of dialog from the film to himself. Though his speech production was fluent and used for a variety of purposes, including social bids, he showed odd tone and volume modulation and could not maintain reciprocity in conversation. During discussion, he often failed to respond to the statements of his conversational partner or commented about his own train of thought. Jonathan’s use of nonverbal communicative behaviors was inconsistent; when highly motivated or engaged in a preferred activity, he directed gaze, expressions, and gestures, to others, but failed to use these behaviors a majority of the time. For example, his gaze was observed to wander about the room when being introduced to others or saying hello. His interest in movies dominated his play interactions in a repetitive fashion. His parents report that, as a younger child, his play consisted of straightforward reenactment of favorite scenes, but he developed the ability to deviate from these scripts and introduce novel twists to the characters’ actions. In play with evaluators, he rigidly directed play, failed to incorporate ideas or requests of his partner, and resisted playing with human figures. At school, he showed an interest in peers, but, partially due to his restricted interests and inflexible style of play, had great difficulty successfully engaging with peers and spent most free time alone. Evaluators ruled out a diagnosis of Asperger’s disorder because Jonathan failed to display verbosity and the strong desire to engage others regarding his area of interest.
Summary
Considerable progress in understanding the biological basis of autism has been made during the last half century. The validity of the disorder is now well established, but knowledge regarding the validity and definition of other ASDs remains quite limited. Continued research is needed to establish diagnostic validity, and the development of highly reliable operational definitions for these disorders and autism remains an important research priority. Brain imaging techniques and genetic studies are likely to continue to elucidate underlying pathophysiological mechanisms. The study of conditions such as CDD may be particularly appropriate to attempt to clarify underlying pathologic mechanisms. At present, it is likely that the diagnostic category reflects multiple etiologic pathways corresponding to the heterogeneous outcomes observed in the disorder.

Introduction

Attention-Deficit/Hyperactivity Disorder (ADHD), Oppositional Defiant Disorder (ODD), and Conduct Disorder (CD) are the most frequently occurring and researched disorders of childhood, and there is an increasing recognition that they continue into adulthood in a subset of individuals (Kessler et al. 2006). ADHD and CD are highly impairing conditions, associated with considerable burden to patients, their families and society. Approximately, 4.4 million children and adolescents, 4–17 years of age, have been diagnosed with ADHD with the estimated annual cost to society of childhood ADHD being $36–52 billion annually (Pelham et al. 2007).

ADHD, ODD, and CD share many core symptoms, associated features, and impairments. Each condition can present with disruptive behavior, academic underachievement, and poor social skills; impulsivity is often present. Consequently, there is a high degree of mutual comorbidity; almost all children with CD also have ODD, and 60–70% of children with ADHD have ODD. Because of their many commonalities, as well as the predominance of disruptive behavior, the three disorders were grouped together in DSM-III-R (American Psychiatric Association 1987), and collectively referred to as the Disruptive Behavior Disorders (DBDs). However, as there is now agreement that ADHD and CD are separable diagnoses with relatively distinct correlates and outcome, and the predominantly inattentive subtype of ADHD is less often associated with disruptive behavior, the class name was changed to Attention-deficit and Disruptive Behavior Disorders (AD-DBDs).

Because of the many similarities in clinical presentation, the high rates of comorbidity, and commonalities related to risk, longitudinal course, and outcome, ADHD, ODD, and CD will be discussed together in this chapter.

Diagnosis

Definition and Diagnostic/Clinical Features

Diagnosis and Core Features

ADHD

ADHD is defined by a persistent pattern of inattention and/or hyperactivity–impulsivity that is more frequently displayed and more severe than is typically observed in individuals at a comparable level of development. There are nine inattention items, six of which are required to meet the symptom threshold. Likewise, there are nine hyperactivity–impulsivity items with the threshold again set at six. Because all the individuals have some of these behaviors at least some
of the time, more in some settings or situations than the others, and because the expected frequency varies as a function of age and gender, it is explicitly stated that behaviors must occur more frequently than the expected in individuals of the same age and gender, in a comparable situation. To highlight the developmental nature of the disorder, at least some symptoms must be present before the age seven. Severity is demonstrated by impairment in social, academic, or occupational functioning, and the occurrence of at least some symptoms in more than one setting.

### DSM-IV-TR Criteria

**Attention-Deficit/Hyperactivity Disorder**

A. Either (1) or (2)

1. Six (or more) of the following symptoms of “inattention” have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:
   - **Inattention**
     (a) often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities.
     (b) often has difficulty sustaining attention in tasks or play activities.
     (c) often does not seem to listen when spoken to directly.
     (d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace.
     (e) often has difficulty organizing tasks and activities.
     (f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort.
     (g) often loses things necessary for tasks or activities.
     (h) is often easily distracted by extraneous stimuli.
     (i) is often forgetful in daily activities.

2. Six (or more) of the following symptoms of “hyperactivity–impulsivity” have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:
   - **Hyperactivity**
     (a) often fidgets with hands or feet or squirms in seat.
     (b) often leaves seat in classroom or in other situations in which remaining seated is expected.
     (c) often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness).
   - **Impulsivity**
     (d) often has difficulty playing or engaging in leisure activities quietly.
     (e) is often “on the go” or often acts as if “driven by a motor.”
     (f) often talks excessively.
     (g) often blurts out answers before questions have been completed.
     (h) often has difficulty awaiting turn.
     (i) often interrupts or intrudes on others.

B. Some hyperactive–impulsive or inattentive symptoms that caused impairment were present before age 7 years.

C. Some impairment from the symptoms is present in two or more settings (e.g., at school[work] and at home).

### Attention-Deficit/Hyperactivity Disorder

ADHD can be diagnosed in individuals of all ages, although it is sometimes difficult to establish the childhood onset of symptoms in older individuals, and to reconcile the manner in which symptoms present in adults with the behavioral descriptions in the predominantly child-oriented item list. There are three subtypes of ADHD, which reflect the nature and relative frequency of current symptoms: Combined (what was previously meant by the term ADHD), Predominantly Inattentive, and Predominantly Hyperactive–impulsive. The latter two subtypes were introduced because the DSM-IV-TR Field Trials found that the children with threshold symptomatology in one domain only had impairment that was not accounted for by other disorders. However, symptoms from both domains are present in the majority of cases, regardless of the subtype.

### ODD

The essential feature of ODD is a recurrent pattern of negativistic, defiant, disobedient, and hostile behavior toward authority figures that persists for at least six months. As in ADHD, behaviors must occur more frequently than is typically observed in individuals of comparable age and developmental level, and accompanied by clinically significant impairment in social, academic, or occupational functioning. The forerunner of ODD, Oppositional Disorder (OD), was first introduced in DSM-III (American Psychiatric Association 1980), and described children who were oppositional but not necessarily disruptive. The list of behavioral descriptors was broadened in the predominantly child-oriented item list. The latter change was intended to distinguish behavior termed pathological from the normal spectrum of oppositional behavior and the minor disruptive acts all children exhibit at one time or other.
CD
CD describes a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated. At least three items from a list of 15 heterogeneous but serious behavioral offenses must be present during the past year, with at least one present in the last six months. The one year time duration reflects the infrequent nature of many of these behaviors. Again, symptoms must be present in more than one setting and cause significant impairment in functioning. Adults with conduct problems may be diagnosed CD, provided they do not meet criteria for Antisocial Personality Disorder (ASPD). Subtypes of CD are determined by age of onset of symptoms. Childhood Onset subtype describes individuals who had at least one of the behaviors before the age 10, while Adolescent Onset subtype describes individuals whose CD behaviors all began after the age 10.

Associated Features and Impairment
In addition to the core (i.e., defining) features of the AD-DBDs there are also many associated features—that is, characteristics which are frequently but not always present, and which extend beyond the boundaries of diagnosis. It is important to appreciate associated features of the AD-DBDs, as these are often highly predictive of impairment. Key associated features include: (i) problems related to learning, academic under-achievement or occupational attainment, (ii) problems in affect regulation, which may include having a “short fuse” or problems in anger management, (iii) being unable to understand or appreciate social cues and other issues related to social context, (iv) problematic family and/or peer relationships, (v) aggression, (vi) low self-esteem, and (vii) substance abuse. The degree to which these features are present likely relates in important ways to the nature and severity of the core features and/or comorbidity, but cannot always be anticipated from these alone. For example, an academic and vocational underachievement may be related to the presence of comorbid learning disorders (LD), but may be seen independent of LD. Persistent

Oppositional Defiant Disorder
A. A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months, during which four (or more) of the following are present:
   (1) often loses temper.
   (2) often argues with adults.
   (3) often actively defies or refuses to comply with adults’ requests or rules.
   (4) often deliberately annoys people.
   (5) often blames others for his or her mistakes or misbehavior.
   (6) is often touchy or easily annoyed by others.
   (7) is often angry and resentful.
   (8) is often spiteful or vindictive.

Note: Consider a criterion met only if the behavior occurs more frequently than is typically observed in individuals of comparable age and developmental level.
B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

Conduct Disorder
A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of three (or more) of the following criteria in the past 12 months, with at least one criterion present in the past 6 months.

Aggression to people and animals
   (1) often bullies, threatens, or intimidates others.
   (2) often initiates physical fights.
   (3) has used a weapon that can cause serious physical harm to others.
   (4) has been physically cruel to people.
   (5) has been physically cruel to animals.
   (6) has stolen while confronting a victim.
   (7) has forced someone into sexual activity.

Destruction of property
   (1) has deliberately engaged in fire setting with the intention of causing serious damage.
   (2) has deliberately destroyed others’ property.

Deceitfulness or theft
   (1) has broken into someone else’s house, building, or car.
   (2) often lies to obtain goods or favors or to avoid obligations.
   (3) has stolen items of nontrivial value without confronting a victim.

Serious violations of rules
   (1) often stays out at night despite parental prohibitions, beginning before age 13 years.
   (2) has run away from home overnight at least twice while living in parental or parental surrogate home.
   (3) is often truant from school, beginning before age 13 years.

B. The disturbance in behavior causes clinically significant impairment in social, academic or occupational functioning.

academic underachievement can lead to school failure, dropping out before graduating or prematurely terminating educational pursuits. Social impairments are frequently present, but need not reflect specific cognitive/skill deficits (e.g., inability to read social cues). Hyperactive-impulsive and aggressive behaviors are often annoying or offensive to others, and resultant peer rejection is seen in all age groups, including preschool children and adults. Cognitive, behavioral, and social impairments associated with the AD-DBDs often have profound effects on psychological development and functional status, with resultant difficulty negotiating age-appropriate developmental tasks. In adolescents and adults, this can include the capacity for forming and maintaining intimate relationships, parenting, educational, and occupational attainment and financial status (Biederman et al. 2006a). Impairments in self-esteem are often but not always present, presumably because self-esteem reflects the interactive effects of several constitutional, psychological, cognitive, social, and family-related variables.

**Assessment**

**Clinical Assessment**
Clinical assessment of the AD-DBDs requires a multisource; multimethod approach. Generally, adults are considered to be the best informants of cognitive and disruptive behavior in children, although older children and adolescents may provide important data regarding inattention, internalizing symptoms, and infrequent or covert behaviors such as antisocial acts. Assessment procedures are similar for ADHD, ODD, and CD, with diagnosis determined from DSM-IV-TR criteria based on information obtained from parents/caretakers and teachers/school professionals regarding the presence and severity of the core symptoms in school, home, and social settings; age of onset; duration of symptoms; and degree of impairment. There are several available structured and semi-structured diagnostic interviews, although these are more often used in research settings. However, regardless of the approach taken in assessment, it is essential to inquire directly regarding the presence and duration of the core symptoms and associated features of the primary disorder, symptoms of frequently occurring comorbid conditions, and the degree to which symptoms cause impairment of age-appropriate developmental functions.

**Rating Scales**
Several professional organizations such as American Academy of Pediatrics (2001) and American Academy of Child and Adolescent Psychiatry (Pliszcz 2007) recommend the use of rating scales in assessment, as they offer an efficient and systematic method of collecting and evaluating clinical information across different settings, in context of age and gender-based norms. Using rating scales during baseline assessment ensures that all symptoms are assessed in a developmentally appropriate manner. Obtaining periodic ratings over the course of treatment is desirable for measuring change in the number and severity of symptoms over time. Concordance of teacher and parent ratings has consistently been found to be in the low- moderate-range. Parents are knowledgeable regarding their child’s day to day behavior at home, including relationships with parents, siblings and peers. Many parents are also knowledgeable regarding their children’s behavior in school, and can be trained to improve the accuracy of their reports. However, regardless of how well informed parents are, teacher ratings provide specific information regarding cognitive and behavioral function in a structured classroom setting, compared with children of the same age and gender in the same situation.

There are many different rating scales which measure behavioral and attentional function in children and adolescents. Broad-based scales survey a wide range of behaviors, and are therefore excellent for comprehensive assessment and screening. Commonly used broad-based scales with solid age and gender-based norms are the Conners (1998a, 1998b) Parent and Teacher Rating Scales, the Achenbach (1991a, 1991b) Child Behavior Checklist and Teacher Report Form, and the Behavioral Assessment Scales for Children (BASC-2) (Reynolds and Kamphaus 2004). In addition to assessing symptoms of ADHD and conduct problems (mainly oppositional behaviors), they have factors describing internalizing symptoms (i.e., depression, anxiety) and several other domains of function (Table 46–1). In addition to rating clinical symptoms, the BASC-2 has a section for adaptive skills (e.g., adaptability, social skills), and a supplemental scale for frontal lobe/executive function. A newer scale that aims to more specifically rate executive function in children of age 5–18 years is the Behavior Rating Inventory of Executive Function (BRIEF) (Gioia et al. 2000). Parents rate children on eight functional domains: inhibitory control, cognitive flexibility, emotional control, initiating tasks or activities, working memory/vigilance, planning/organization, organizing materials, and self-monitoring capacity.

Other rating scales for ADHD more specifically evaluate DSM symptoms—including the Swanson, Nolan, and Pelham (SNAP) Parent and Teacher Rating Scales (Swanson 1992), the ADHD Rating Scale (ADHD-RS-IV), parent and teacher versions (DuPaul and Stoner 1994) and the Vanderbilt ADHD Parent and Teacher Ratings Scales (Wolraich et al. 2003, Wolraich et al. 1998). These scales provide dimensional ratings of DSM symptoms which closely coincide with interview-based diagnoses of ADHD. In addition, the SNAP-IV and Vanderbilt include the DSM ODD items, and the Vanderbilt covers a variety of other mood, anxiety and conduct problem behaviors. Similar to these DSM-based instruments, the revised Conners has subscales for DSM total, DSM-inattention and DSM-hyperactivity/impulsivity symptoms to maximize compatibility with DSM-IV-TR diagnosis.

Several rating scales have been developed to measure the spectrum of oppositional/aggressive behavior. The Inattention, Overactivity With Aggression (IOWA) Conners (Loney and Milich 1982, Pelham et al. 1989) is comprised of 5 items from the Conners which are (relatively) divergently valid for inattention/cognitive impairment, and 5 items which are divergently valid for aggression. The New York Teacher Rating Scale (Miller et al. 1995) includes the DSM items for both ODD and CD, as well as a number of other disruptive and/or aggressive behaviors (Table 46–2). The Overt Aggression Scale (OAS) (Yudofsky et al. 1986) is an observer-rated instrument originally designed to measure aggressive behavior in inpatient settings. The Over Aggression Scale-Modified (OAS-M) (Coccaro et al. 1991) obtains this information via self/other report format suitable for outpatient settings, but with little validating data in children.
### Table 46–1 Frequently Used Rating Scales for Assessment of ADHD and ODD Symptoms

<tbody>
<tr>
<td><strong>Child/Adolescent</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Revised Conners Parent and Teacher Rating Scales</td>
<td>Broad-based scale; most frequently used for ADHD and oppositional behavior; also rates internalizing symptoms; some aggression items load with internalizing behaviors (e.g., emotional lability); gender-based norms for children of age 3–17</td>
<td>Multi Health Systems, Inc., <a href="http://www.mhs.com">www.mhs.com</a></td>
</tr>
<tr>
<td>Achenbach Child Behavior Checklist (CBCL) and Teacher Rating Form (TRF)</td>
<td>Broad-based scale with separate factors for ADHD, aggression, delinquency; excellent for screening; gender-based norms for children of age 4–18 years; separate scale for 2 and 3 year olds</td>
<td>Achenbach System of Empirically Based Assessment (ASEBA), Inc., <a href="http://www.ASEBA.org">www.ASEBA.org</a></td>
</tr>
<tr>
<td>BASC-2</td>
<td>Broad-based scale; has sections for clinical symptoms, adaptive skills (e.g., adaptability, social skills), and frontal lobe/executive function (supplemental scale).</td>
<td>AGS Publishing, Inc., <a href="http://www.agsnet.com">www.agsnet.com</a></td>
</tr>
<tr>
<td>SNAP-IV</td>
<td>Rates frequency and severity of ADHD on a single 0–3 scale; 18 items correspond to the actual DSM-IV-TR criteria; DSM-IV-TR iteration includes ODD items; used in MTA study</td>
<td><a href="http://www.adhd.net/snap-iv-form.pdf">www.adhd.net/snap-iv-form.pdf</a></td>
</tr>
<tr>
<td>ADHD-Rating Scale (Parent; Teacher versions)</td>
<td>Like SNAP; rates frequency and severity of DSM ADHD symptoms; has been used in adults but items are not developmentally sensitive, and norms for children and adolescents only; used as an investigator-administered interview in several clinical trials of ADHD medications</td>
<td>Guilford Press, <a href="http://www.guilford.com">www.guilford.com</a></td>
</tr>
<tr>
<td>Vanderbilt ADHD Rating Scale (Parent and Teacher versions)</td>
<td>Similar to SNAP-IV and ADHD-RS for ADHD, but also has the DSM items for ODD, 12 criteria for CD, 7 screening criteria for anxiety/depression, and 8 additional items for academic performance and social function</td>
<td><a href="http://www.peds.mc.vanderbilt.edu/VCHWEB_1/rating-1.html">www.peds.mc.vanderbilt.edu/VCHWEB_1/rating-1.html</a></td>
</tr>
<tr>
<td>BRIEF</td>
<td>Parent report of executive function in children of age 5–18 years; measures eight domains: inhibitory control, cognitive flexibility, emotional control, initiating tasks or activities, working memory/vigilance, planning/organization, organizing materials, and self-monitoring capacity.</td>
<td>Psychological Assessment Resources, Inc., <a href="http://www.parinc.com">www.parinc.com</a></td>
</tr>
<tr>
<td><strong>Adolescent Self-Report</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>YSR (Achenbach)</td>
<td>Self-report scale based on the Achenbach.</td>
<td>Achenbach System of Empirically Based Assessment (ASEBA), Inc., <a href="http://www.ASEBA.org">www.ASEBA.org</a></td>
</tr>
<tr>
<td><strong>Adult</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Brown ADD Scale</td>
<td>Rates inattention/executive dysfunction; items extend beyond DSM definition; 5 domains: organizing work, sustaining attention and concentration, sustaining alertness and effort, managing frustration and other emotions, and using working memory; good for high functioning adults with inattentive subtype</td>
<td>The Psychological Corporation, <a href="http://harcourtassessment.com">http://harcourtassessment.com</a></td>
</tr>
<tr>
<td>Conners Adult ADHD Rating Scale</td>
<td>Large item set of developmentally relevant items; extends beyond DSM definition, but DSM subscale maps onto diagnosis; self-report and “other-report” versions</td>
<td>Multi Health Systems, Inc., <a href="http://www.mhs.com">www.mhs.com</a></td>
</tr>
<tr>
<td>Wender–Reimherr Adult Attention Deficit Disorder Scale</td>
<td>Retrospective symptom scales provide age of onset data; less clearly tied to DSM-IV-TR ADHD.</td>
<td>Fred W. Reinherr, MD, Mood Disorders Clinic, Department of Psychiatry University of Utah Health Science Center Salt Lake City, UT, USA</td>
</tr>
<tr>
<td>Barkley’s Current Symptoms Scale</td>
<td>Dimensional scale linked to semi-structured interview; uses actual DSM items but not re-worked for adults; rates behavior in the past 6 months; self and other informant reports.</td>
<td>Barkley and Murphy (1998)</td>
</tr>
<tr>
<td>Adult Self-Report Scale v1.1 (18-item symptom assessment and 6-item screener)</td>
<td>18 ADHD item self-report scale and 6 item screener; developmentally relevant for adult manifestations of ADHD symptoms; rates frequency, not severity, on a 0–4 scale</td>
<td><a href="http://www.med.nyu.edu/Psych/traing/adhd.html">www.med.nyu.edu/Psych/traing/adhd.html</a> and website of the World Health Organization, Geneva, Switzerland</td>
</tr>
<tr>
<td>Adult Investigator Symptom Report Scale (AISRS)</td>
<td>Interviewer administered dimensional scale; rates 18 DSM-IV-TR ADHD criteria; developmentally sensitive for adult manifestations; 6 ASRS screen items are stem questions, followed by the other 12</td>
<td>Lenard Adler, MD, Adult ADHD Program NYU School of Medicine New York, NY, USA <a href="mailto:adultADHD@med.nyu.edu">adultADHD@med.nyu.edu</a></td>

</table>
The Buss–Perry Aggression scale (Buss and Perry 1992) is a self-report measure which has been used in adolescents as well as adults, and provides information on four domains of aggressive behavior: physical aggression, verbal aggression, anger, and hostility. The Children’s Aggression Scale (CAS), parent (Halperin et al. 2002) and teacher (Halperin et al. 2003) versions, likewise measures the full range of physically aggressive behavior, but was specifically developed for use in children and adolescents. There are five factors: verbal aggression, aggression against objects and animals, provoked physical aggression, unprovoked physical aggression, and use of weapons.

Despite their many benefits, rating scales have several limitations. Contextual and categorical features of diagnostic categories are often not included, and low frequency or episodic behaviors can be missed. In addition, raters often differ in their threshold for considering different behaviors to be problematic, and behavior differs across situations. The resultant low level of agreement is often considered to be a limitation. However, it illustrates the importance of obtaining information from multiple informants, across multiple settings. Most importantly, rating scale data should be used to augment information obtained from direct clinical assessment, and should not be used alone for purposes of diagnosis.

**Structured Assessment Methods for Adult ADHD**

There are now several structured rating scales and diagnostic interviews to aid in the assessment of ADHD in adults, which evaluate symptoms in a developmentally appropriate manner. This is important because symptoms often present differently in adults than children, and the threshold for determining when symptoms cause impairment is often different in adults (Table 46–1).

The Conners Adult ADHD Rating Scale (Conners et al. 1999) and Wender–Reimherr Adult Attention Deficit Disorder Scale (Wender 1995) are self-report scales which assess a wide range of developmentally relevant symptoms for ADHD and associated behaviors. The Conners has a DSM subscale that maps onto the ADHD diagnosis fairly well. Also, the Conners is available in self-report and “other-report” formats, the latter for completion by a spouse or significant other—analogous to parent and teacher reporting in children. The Wender–Reimherr includes items that retrospectively assess childhood onset of symptoms. Other adult ADHD rating scales utilize actual DSM items, or adaptations of these items, in a dimensional format.
including: 1) the Barkley Current Symptoms Scale (Barkley 1998) and the ADHD-RS (DuPaul et al. 2001), each of which uses the actual 18 DSM-IV-TR items; 2) the Adult ADHD Self Report Scale (ASRS) v1.1 Symptom Checklist (Kessler et al. 2005), which is derived from the same DSM items but adapts them for use by adults in an 18 item self-report format and a 6-item screener, and 3) the Adult ADHD Investigator Symptom Rating Scale (Adler and Cohen 2004); a symptom-based interview that utilizes adult specific stem questions for different ADHD domains and adult specific prompts. The ASRS was developed in collaboration with the World Health Organization, reflecting the high level of attention that ADHD has received world-wide. Finally, the Brown Attention-Deficit Disorder (ADD) scales (Brown 1996) assess the presence, severity and consequences of cognitive and executive dysfunctions in a self-report format. Corresponding scales for use in children and adolescents have also been developed (Brown 2001).

Currently available structured or semi-structured interviews for ADHD in adults include the Conners Adult ADHD Diagnostic Interview (CAADID) (Epstein and Kollins 2006), the Barkley Current Symptoms Scale (Barkley 1998), the Brown ADD Scale Diagnostic Form (Brown 1996) and the Adult Clinician Diagnostic Scale (ACDS) v1.2 (Adler and Cohen 2004). The ACDS is an adaptation of the Kiddie-SADS ADHD module (which had previously been used to assess adults as well as children, since the main structured interviews for adults did not include ADHD) utilizing developmentally appropriate prompts specific for adult ADHD. Consequently, the ACDS v1.2 has been used in more recent ADHD trials.

Neuropsychological Assessment

Neuropsychological testing is not required to diagnose ADHD, ODD or CD. However, neuropsychological and/or educational tests of cognitive, linguistic, perceptual, motor and academic functioning can be used to augment the clinical assessment of attentional function, to provide normed data required for the diagnosis of mental retardation and specific learning disabilities, and to assess the adequacy of school placement. Furthermore, testing is often required to justify the need for supplemental services or to request accommodations during exams or standardized tests (i.e., extended time, other special circumstances). Intellectual capacity or intellectual quotient (IQ) and academic achievement are both routinely assessed, using tests such as the Wechsler Intelligence Scale for Children (i.e., WISC-IV, or the Wechsler Adult Intelligence Scale (i.e., WAIS) and the Wechsler Individual Achievement Test (i.e., WIAT), respectively. Additional assessment of executive functions such as vigilance, working memory and cognitive conflict resolution is often undertaken, using tests such as the Continuous Performance Test, Wisconsin Card Sorting Test, Stroop Word-Color Association Test, and Test of Working Memory. Because tests of executive function lack specificity, and because only a subgroup of individuals with ADHD have executive function deficits, these tests should not be used for purposes of diagnosis. However, it is important to identify individuals with neurocognitive disabilities and provide appropriate remediation, as the presence of comorbid executive function deficits and ADHD is associated with a high degree of impairment (Biederman et al. 2006b).

Laboratory Measures

There are no physical findings or laboratory measures which reliably distinguish the AD-DBDs from each other, other disorders or normal controls. However, since several medical conditions can mimic ADHD, obtaining targeted laboratory assessments may be useful. Routine screening for thyroid disorders had been advocated; based on the findings indicating a high association of generalized resistance to thyroid hormone and ADHD in several families. However, the vast majority of individuals with ADHD do not have abnormal thyroid function, and whether to obtain thyroid indices should be guided by clinical presentation. Similarly, while research studies have used neuroimaging methods to identify characteristic patterns of brain structure or function in individuals with ADHD and CD, findings to date have neither been consistent nor specific enough to recommend that these methods be used for diagnosis.

A variety of objective devices, such as wrist actometers and acceleration-sensitive actographs, have been used to quantify activity level in individuals with ADHD, ODD and CD. These devices provide judgment-free assessments of activity level and can be used to evaluate the accuracy of information obtained from clinical interviews and rating scales. Actigraphs also have intuitive appeal for use in clinical settings; they are relatively small, and interface with computer software which download and analyze data. Actigraph measures in children, obtained during a one hour neuropsychological test session in an outpatient setting, were found to have high specificity but relatively lower sensitivity relative to clinical diagnosis (i.e., many false negatives). Actigraphs therefore cannot be used alone to diagnose ADHD. However, they could have a role in augmenting interpretation of data obtained from measures which have high sensitivity and low specificity (i.e., good for screening, but many false positives), such as continuous performance tests of vigilance.

A measure which has recently been used in research settings to quantify on-task behavior and task completion is the Permanent Product Measure of Performance (PERM-P) (Wigal and Wigal 2006). Children are instructed to complete mathematics worksheets containing a large number of problems within a specified time period. Measures of interest include both the number of problems attempted and the number completed correctly. Since the PERM-P is not intended to measure mathematics ability or intelligence, but rather task completion, it is essential that the problems be simple enough to be considered rote and boring. Therefore, several different sets of problems are available, based on the child's grade level. Children with ADHD treated with medication have been shown to complete more math problems, without sacrificing accuracy, in several studies.

Structured observation approaches have been used in both playroom and school settings to provide a quantitative assessment of behavior. Structured playroom assessments quantify activity level by recording the number of times the child crosses grids marked on the floor, touches toys that he/she is told not to use, and the amount of time spent on a particular task. In school settings, trained raters are used to quantify the amount of time children with ADHD spend on-task, in their seats, etc., often in comparison with non-ADHD children. These quantitative approaches are quite time consuming and do not translate easily to the clinical setting. However, less structured observation of children's...
classroom behavior is not infrequently undertaken as part of a comprehensive clinical evaluation, particularly in challenging cases.

**Epidemiology**

ADHD, ODD, and CD are all highly prevalent disorders, although there is considerable variability across studies, reflecting not only differences in populations but also variability in assessment methods and the definition of case-ness. In preschool children, the prevalence of ADHD is estimated to be 2%–8%. The rate increases to 4%–12% in elementary school-age children and declines in adolescence to about 6%. The first large epidemiologic study of ADHD in adults in the U.S. found the prevalence to be 4–5%, or approximately 60% what it is in school-age children (Kessler et al. 2006). Impairment from residual symptoms is common in adulthood; approximately two-thirds of the children with ADHD continue to have some symptoms causing impairment as adults, even if they do not meet criteria for the full diagnosis. The prevalence of ADHD is quite stable world-wide, with rates that are comparable to those in the US, in both industrialized and developing countries, when similar instruments are used (Faroone et al. 2003).

The lifetime prevalence of ODD is estimated to be 10.2%, and is somewhat higher for males (11.2%) than females (9.2%). The presence of either active or remitted ODD significantly predicts subsequent onset of other disorders. Virtually all children with ADHD (92.4%) also meet criteria for at least one other lifetime DSM-IV-TR disorder, including: mood (45.8%), anxiety (62.3%), impulse-control (68.2%), and substance use (47.2%) disorders. Both early onset ODD (before age 8) and ODD plus comorbidity predict a more chronic course, with less robust and less immediate improvement following treatment (Nock et al. 2007). The prevalence of CD is considerably lower than ODD in childhood, with rates estimated to be as low as 1% in school age children but increasing several fold in adolescence. The percentage of boys with conduct problems in an epidemiological study of ADHD in elementary school-age children and declines in adolescence is approximately 60% what it is in school-age children (Kessler et al. 2006). Impairment from residual symptoms is common in adulthood; approximately two-thirds of the children with ADHD continue to have some symptoms causing impairment as adults, even if they do not meet criteria for the full diagnosis. The prevalence of ADHD is quite stable world-wide, with rates that are comparable to those in the US, in both industrialized and developing countries, when similar instruments are used (Faroone et al. 2003).

The lifetime prevalence of ODD is estimated to be 10.2%, and is somewhat higher for males (11.2%) than females (9.2%). The presence of either active or remitted ODD significantly predicts subsequent onset of other disorders. Virtually all children with ADHD (92.4%) also meet criteria for at least one other lifetime DSM-IV-TR disorder, including: mood (45.8%), anxiety (62.3%), impulse-control (68.2%), and substance use (47.2%) disorders. Both early onset ODD (before age 8) and ODD plus comorbidity predict a more chronic course, with less robust and less immediate improvement following treatment (Nock et al. 2007). The prevalence of CD is considerably lower than ODD in childhood, with rates estimated to be as low as 1% in school age children but increasing several fold in adolescence. The percentage of boys with conduct problems in an epidemiological study of ADHD in elementary school-age children and declines in adolescence was 10.5% (Odagers et al. 2007). Several other subgroups were identified: 19.6% developed conduct problems for the first time during adolescence; 24.3% had conduct problems in childhood but subsequently desisted; and 45.6% had persistent but low levels of conduct problems (45.6%) and did not meet criteria for CD. Findings from this and numerous other studies have shown that early onset conduct problems contribute a risk for later in life antisocial behaviors, accidents, disease, health problems and mortality, while some have hypothesized that such risk is related to CD regardless of age of onset.

**Comorbidity Patterns**

Conduct problems, including oppositional behavior, defiance, aggression and delinquency, account for the majority of comorbidity in children with ADHD. Data from several epidemiological studies (Maughan et al. 2004) indicate that ODD and CD are present in 40–70% of the children with ADHD. These comorbidity figures are not unidirectional. Among children with ODD and/or CD in these same studies, 40–60% also had ADHD. In addition, the percentage of children with ADHD and comorbid disruptive behavior (i.e., some clinically significant problems are present, but the full diagnosis is not met) is greater still. The prevalence of comorbid ADHD/ODD/CD/aggression is thought to be higher in clinical than epidemiologic samples, since the co-occurrence of these conditions is highly impairing and often leads to referral. Rates of comorbidity appear to vary across clinical settings, with an over-representation in psychiatric compared to pediatric settings.

Lifetime rates of comorbid depression and anxiety are also quite high among children with ADHD, with published prevalence rates of 15–35% for depression and 25–50% for anxiety disorders (Spencer et al. 2007b). Consistent with the longitudinal course of depression and anxiety disorders, the prevalence of these conditions increases in individuals with ADHD during adolescence and adulthood. Both comorbid depression and anxiety must be distinguished from the consequences of chronic underachievement, such as demoralization and fearful anticipation secondary to chronic poor performance. Other neuropsychiatric conditions which frequently co-occur with the AD-DBDs include Tourette's disorder (TS) and developmental LD. Approximately 50–60% of individuals with TS also have ADHD, and many of these have ODD or CD as well. A much smaller percentage of individuals with TS also have ADHD, owing to differences in prevalence of the two conditions. The rates of specific LD among youth with ADHD range from 20–90%, with the lower figure reflecting actual LD and the higher rates indicative of more broadly defined academic underachievement. Academic underachievement is also highly prevalent among youth with CD, although rates of actual LD are lower. Rates of school drop-out are also elevated, often in association with a confluence of psychosocial as well as cognitive risk factors.

The extent to which ADHD and bipolar disorder occur comorbidly has been controversial, with prevalence rates in some samples estimated to be 15% or higher (Spencer et al. 2007b). However, prevalence estimates in other samples are much lower. These discrepancies may in part reflect potential symptomatic overlap, as well as the manner in which symptoms of bipolar disorder are operationalized. Youth with ADHD + bipolar disorder generally present with mood lability, agitation, conduct problems, and various other impairments. They do not typically cycle like later onset bipolar patients, but rather have severe behavioral dysregulation. These children almost always meet criteria for CD as well. It is not clear whether children diagnosed with ADHD + comorbid bipolar disorder are neurobiologically similar to those with more classic symptoms of bipolar disorder, and whether these children develop more classical bipolar disorder later in life. Comorbidity with ADHD is extremely common among children with bipolar disorder, occurring up to 90% of the time. In adolescent onset bipolar disorder, comorbidity with ADHD remains high, but is substantially lower than in the child-onset group.

It is well known that depression in children is frequently comorbid with the acute onset of behavior problems, with 60% of youth with major depression meeting criteria for CD. In addition, it is well known that anxiety and depression frequently co-occur. The co-occurrence of ADHD with these other disorders is also not uncommon, meaning that three or more disorders are often present. For example,
approximately two-thirds of the children with ADHD and comorbid anxiety disorders in the Multimodal Treatment Study of Children with ADHD (MTA) also had CD (March et al. 2000). In both this sample and others, the symptomatic and functional status of children with ADHD plus anxiety disorder is altered when CD is also present (Newcorn et al. 2004). Consistent with this observation, individuals with ADHD and comorbid internalizing and externalizing disorders had the highest degree of impairment in the MTA study (Jensen et al. 2001).

In addition to psychiatric comorbidity, a variety of medical conditions can co-occur with ADHD, including epilepsy, sleep disorders, thyroid disease, post-infectious and/or post-traumatic encephalopathy and sensory impairments. More often, it is important to rule out these conditions. Finally, many medications which are prescribed to children can mimic the symptoms of ADHD and/or ODD. Examples include anticonvulsants (e.g., phenobarbital), antihistamines, decongestants, bronchodilators (e.g., theophylline) and systemic steroids. Before diagnosing ADHD in the presence of these and other medical conditions, it is essential to determine that the ADHD symptoms are not better accounted for by the other condition and/or its treatment, and that the trajectory of ADHD symptoms follows an independent longitudinal course.

Course

ADHD

Many symptoms of ADHD are observable during the preschool years, with hyperactivity–impulsivity and aggression predominating. Attentional symptoms are usually reported after hyperactivity–impulsivity symptoms. However, it is likely that these behaviors are present from early on but are not reported until the child enters school, when there are increased environmental and cognitive demands. Hyperactivity–impulsivity symptoms are frequently associated with oppositional behaviors, giving the appearance of a simultaneous, rather than a sequential onset. Approximately two-thirds of the children with ADHD continue to have attentional, behavioral, and emotional problems well into adolescence and adulthood. Inattention symptoms remain high, and can be associated with difficulty working independently, poor academic performance and educational attainment, unemployment and/or lower occupational status, and lower earning potential. Inattention and related impairments drive treatment in the large majority of adults with ADHD. Hyperactivity–impulsivity symptoms generally decline in adolescence but can be highly impairing when they persist—even if they are “subthreshold.” Functional consequences of persistent hyperactivity–impulsivity may include impairments in driving, early sexual activity, sexually transmitted diseases, early pregnancy, substance abuse and delinquent behavior, all of which are elevated in samples of ADHD children followed longitudinally (Barkley et al. 2006). These represent some of the most challenging long-term sequelae of ADHD, although these outcomes most often occur in individuals with ADHD and comorbid CD. Families of these children tend to be less stable, have higher divorce rates, and move more frequently. First-degree relatives have been found to have higher rates of antisocial behaviors, substance abuse, and depression.

ODD/CD

The developmental course of oppositional behavior is highly variable. During the preschool years, transient oppositional behavior is very common. However, if oppositionality persists, there is heightened risk for escalation to more clinically significant disruptive behavior. There are two possible developmental trajectories. In most oppositional children, who are usually not physically aggressive, oppositional behaviors peak in mid-childhood, around the age 8 and decline after that. In others, oppositional behavior escalates to delinquent behaviors (Burke et al. 2002). The early presentation of physical aggression is a key predictor of this latter trajectory, as physically aggressive children are more likely to progress from early oppositional behaviors to more severe and disabling conduct problems. Coexistent ADHD speeds the escalation to more severe conduct problems, resulting in elevated rates of ASPD and substance use disorders in adulthood.

The developmental course of CD is highly gender dependent. In boys, symptoms of CD often begin in preschool years, with age of onset peaking in mid-childhood. There are substantial individual differences in the adolescent outcomes of CD, ranging from worsening to sustained recovery, (Lahey et al. 2002). The development of conduct problems typically follows a progressive course, beginning with rule violations, such as poor school attendance, and escalating to aggression towards animals and people. In girls, CD symptoms are less often aggressive in nature and have their onset at a later age. Longitudinal studies have found that the childhood-onset (<12 years) CD in girls may be predicted by paternal ASPD, while adolescent-onset CD (≥12 years) tends to be associated with family conflict. In addition, lifetime CD significantly predicts academic, psychiatric and sexual behavior problems in girls with ADHD at follow-up. (Monuteaux et al. 2007). When CD begins in adolescence, the problems are likely to diminish by adulthood. However, CD which begins in preschool or childhood years is more likely to persist and escalate to antisocial, delinquent and criminal behavior. (Satterfield et al. 2007). Recent findings suggest that family-genetic risk factors play a stronger role in the occurrence of childhood onset CD, while family-environmental risk factors are more salient in the incidence of adolescent-onset CD (Spencer et al. 2007b).

Differential Diagnosis

There is very little overlap in the defining characteristics of ADHD, ODD and CD. However, the frequent co-occurrence of inattention, hyperactivity, impulsivity, oppositionality and aggression suggests that these symptoms are closely related, and therefore difficult to disentangle both heuristically and in clinical practice. Nevertheless, the distinctiveness of ADHD and CD has been demonstrated in several epidemiologic studies (Maughan et al. 2004) which have examined correlates of the two conditions. Children with ADHD have a persistent pattern of developmental problems and cognitive impairments, while those with CD more often come from lower SES backgrounds and experience high levels of psychosocial adversity. These findings are consistent with the hypothesis that CD may be a more environmentally driven condition than ADHD, although they do not preclude genetic/neurobiologic contributions to the pathogenesis of CD, as well as psychosocial mechanisms for ADHD.
Data from both epidemiologic and clinical studies indicate that children who are comorbid for ADHD and CD present with risk factors and associated features characteristic of both disorders, consistent with data (Maugan et al. 2004) which indicate that comorbid CD accounts for the poorest outcome among children with ADHD, and conversely, that comorbid ADHD confers increased risk for poor outcome in children with CD.

The core symptoms of ADHD and ODD are also not identical, despite the very high rate of comorbidity. For example, ODD symptoms, such as “loses temper,” “actively defies,” and “swears” are not characteristic of children with ADHD only, and can therefore be used to distinguish the two disorders. Children with ADHD who have high levels of hyperactive/impulsive symptoms are at greatest risk for also having ODD. Nonetheless, approximately 30% of the children with ADHD and comorbid ODD have predominantly inattentive subtype (Newcorn et al. 2005).

Because 90% of the children with CD also meet criteria for ODD, the two conditions are not diagnosed together. The fact that virtually all youth with CD also have ODD led to the hypothesis that ODD represents a developmental precursor of CD. However, the majority of children with ODD do not develop CD, supporting the existence of independent diagnoses. In cases where ODD precedes CD, the onset of CD is typically before the age 10 (childhood onset CD). In children with onset of CD after the age 10, symptoms of ODD and ADHD are usually not present during early childhood. It has been shown that children with ODD demonstrate less impairment and are more socially competent than children with CD. Children with CD generally come from less advantaged families and have greater conflict with school and judicial systems than those with ODD only. Family adversity scores in children with ODD are usually intermediate between those of children with CD and normal children.

Symptoms of ADHD overlap with several other psychiatric diagnoses. Generalized anxiety disorder is often characterized by agitation and restlessness, as well as inattention to salient stimuli. However, these symptoms generally occur in response to some perceived fear stimulus, and do not reflect the individual’s overall capacity for self-regulation and information processing, as in ADHD. Likewise, decreased concentration and poor academic achievement are frequently present in major depression and other mood disorders. Depressive disorders are often episodic, and while academic decline is often present in both disorders, it is more often acute and precipitous in depressive disorders. Nevertheless, youth with major depression often also have dysthymia, and academic achievement in individuals with ADHD may vary from one school year to the next. Consequently, chronicity of course may not distinguish the two conditions. Age of onset of academic impairment is generally earlier in ADHD. However, when ADHD is present in individuals with high IQ, particularly those with predominantly inattentive subtype, onset or recognition of symptoms may be later.

Finally, although it would not seem difficult to distinguish ADHD and schizophrenia, it is not uncommon for child-onset schizophrenia to present with a variety of negative symptoms including inattention, underachievement and lack of motivation, which are also present in a subset of youth with predominantly inattentive ADHD. Similarly, youth with Asperger’s disorder often present with inattention symptoms, and their aloofness can be misinterpreted as a reflection of inattentiveness. The nature of social impairment and the developmental course of symptoms can often distinguish the disorders. However, it is also possible that symptoms of both conditions are present.

**Differences in Developmental, Gender, and Cultural Presentations**

In school age children, boys have higher rates than girls for all three disorders. The combined subtype accounts for the majority of cases of ADHD in both genders, although the relative proportion of cases with inattentive subtype is higher in girls than boys. In clinic settings, the ratio of boys to girls is about 9:1, but in community samples, this decreases to approximately 3:1. Teachers tend to identify fewer girls than boys as having ADHD symptoms, presumably because girls are less often disruptive. In ADHD children with predominantly hyperactive–impulsive subtype, the male to female ratio is approximately 4:1 (Gershon 2002). The gender ratio falls to 2:1 in the predominantly inattentive subtype. For both genders, the prevalence of the full syndrome declines with age, with predictors of persistence including severity of ADHD in childhood, family history of ADHD and comorbidity (Barkley et al. 2006). Cross-sectional prevalence estimates in referred samples of adults indicate that males and females are equally affected, which suggests that different types of patients may present for treatment in childhood and adulthood.

There are also important gender differences in the clinical presentation and longitudinal course of ODD and CD. Most studies have found that early onset CD is much more characteristic of boys than girls, primarily due to the fact that boys are more physically aggressive than girls. Consistent with this observation, CD in girls is much less directly confrontational than in boys, with “relational” aggression more often present (Ohan and Johnston 2005). Recent longitudinal findings indicate that the prevalence of new onset CD in adolescence is higher in girls than boys, and the overall rates of CD are not different in girls and boys by mid-late adolescence. However, the higher rates of childhood onset CD among girls in some studies suggest that there are multiple pathways to CD in girls.

An accumulation of data support the contention that ADHD is a worldwide disorder, with findings of similar prevalence (approximately 5%) in the developed and the developing countries, from both Western and Eastern hemispheres (Faraoe et al. 2003). However, in US studies, there appear to be cultural differences in the degree of acceptance of both the diagnosis and its treatment, as well as differences in access to care (National Institutes of Health 2000). For example, the use of stimulants in school age boys is approximately twice as high in Caucasians as compared with African-Americans. Further, data from several regional studies examining patterns of stimulant medication use highlight the extent to which treatment in different communities is divergent.

**Etiology and Pathophysiology**

**Genetic Factors**

Several parallel lines of research document the prominent role of genetics in the etiology of the AD-DBDs, and further
suggest that these disorders may share common familial vulnerabilities. The heritability of ADHD was determined to be 0.76 in a meta-analysis of data from 20 twin studies (Faraone et al. 2005), which is almost as high as the heritability for schizophrenia, and substantially higher than for many psychiatric disorders. While some reports have estimated the heritability for childhood antisocial behaviors to also be equally high, results of most other studies suggest that it is more moderate, that is, 0.3–0.7 (Slutske et al. 1997).

Findings from pharmacological, neuroimaging and animal studies implicating dopaminergic and noradrenergic neural circuits in the pathophysiology of ADHD have inspired a large number of gene association studies. Candidate genes related to DA neurotransmission found to be positively associated with ADHD include the dopamine receptor D2 (DRD2), D4 (DRD4), and D5 (DRD5) receptor genes as well as the dopamine transporter. In addition, candidate genes related to release (SNAP-25) and metabolism of DA (e.g., Catechol-O-methyl transferase (COMT), Monoamine oxidase-A (MAO-A)) are associated with increased risk for ADHD. The association of the DRD4 gene with ADHD has been the best replicated and most robust thus far. The high risk polymorphism, 7-repeat allele, was found to have an odds ratio of 1.4 in a meta-analysis of 8 case-control and 14 family studies (Faraone et al. 2005). There has also been relatively high agreement regarding the association of SNAP-25 (i.e., synaptosomal-associated protein 25 gene, which is a neuron-specific protein implicated in exocytotic catecholamine release) and ADHD. The possible involvement of COMT in ADHD is of particular interest, given the role of COMT in aggression and substance abuse risk, the frequent comorbid occurrence of ADHD and CD, and the relationship of this comorbidity to risk for adolescent addiction. At the same time, some of the initial enthusiasm that followed from positive findings in relatively low n studies with other candidate genes has waned, as preliminary positive reports have either not replicated or have been found to have little predictive value. For example, the odds ratio in a recent meta-analysis of DAT1 across numerous studies was only 1.04 (Li et al. 2006).

Some of the above candidate genes have also been examined in pharmacogenomic studies. The first such report found the homozygous 10-repeat allele of DAT1 to be associated with lower response to methylphenidate (MPH). However, results of subsequent studies have been equivocal. Although there have been several replications, two recent studies did not support any association of DAT1 and MPH response, and one other suggested an association of the 9,9 polymorphism with nonresponse (Stein et al. 2005). There have been fewer studies examining response to MPH as a function of DRD4 genotype. In one study, the likelihood of response was not different as a function of DRD4 genotype, but the presence of one or two copies of the 7-repeat allele was associated with higher MPH dose (Hamarman et al. 2004), supporting the hypothesized role of DRD4 in mediating a blunted intracellular response to DA.

A number of studies have also examined the role of noradrenaline (NE)-related genes in ADHD, given the strong evidence from basic science investigations regarding the role of NE in cognitive/attentional processes and ADHD (Arnsten 2006). Initial investigations did not find an association between ADHD and the norepinephrine transporter gene (NET), adrenergic 2A (ADR2A), or the adrenergic alpha 1C and 2C receptor genes. However, emerging evidence supports positive associations of ADHD with the NET1, the Taq 1 polymorphism within the gene for DBH (the enzyme which converts DA to NE), and several studies have found an association with the ADR2A gene—particularly as regards cognitive deficits and/or learning. In addition, the ADR2A gene has been found to predict response to MPH (Polanczyk et al. 2007), consistent with findings from animal studies indicating that that MPH enhances NE as well as DA. Finally, the association of ADHD with DRD4 genotype could possibly reflect the role of the DRD4 receptor in regulating noradrenergic neurotransmission, as NE is a potent agonist of the DRD4 receptor.

There have also been positive associations of ADHD and various serotonin system genes, including the serotonin transporter (5-HTT or SLC6A4) and the serotonin receptor 1B, 1D, and 2A genes (Faraone and Khan 2006), although not consistently so. It is interesting to consider whether variability in findings related to 5-HT genotype could reflect sample differences related to the presence of comorbid CD. This would be consistent with findings pointing to the familial basis of childhood conduct problems. Likewise, differences attributable to gender could contribute to variability across studies. Results from an Australian cohort of 889 twin families found an environmentally mediated role of parental conduct problems in the etiology of behavior problems in males, while common genetic risk accounted for the entire intergenerational transmission in females (D’Onofrio et al. 2007). A similar gender specific dissociation was reported in 87 adopted children, (Cadoret et al. 2003) linking the serotonin-transporter promoter region (5HTTLPR) with other genetic risk factors and behavioral disturbances. A possible gender-related interaction with 5HTTLPR was suggested by differential association between the 5HTTLPR short variants (SS or SL) and symptom counts for CD, aggression and ADHD as a function of gender; the association between ADHD and the short 5HTTLPR genotype was higher in males and lower in females. In addition, there was an increased risk for the externalizing behavior in individuals with the long (LL) variant of 5HTTLPR and antisocial biologic parentage, and also increased risk for externalizing behavior in individuals with one or more 5HTTLPR short variants (SS or SL) in conjunction with a genetic diathesis for alcoholism.

The hypothesized association between CD and 5-HT candidate genes is based on the well-accepted role of 5-HT neurotransmission in modulating impulsive/aggressive behavior. Positive findings for several 5-HT system genes (e.g., 5-HT transporter and 5-HT receptor 1B and 2A genes) have been reported in relation to impulsive/aggressive behaviors, but not all studies have categorically linked genotype to CD. These findings suggest the importance of genetic factors in the development of CD, and point to a possible role for 5-HT, but additional research is required.

**Neurobiological Factors**

Recent advances in neuroimaging implicate neural circuits centered in the prefrontal cortex and striatum, as well as the brainstem catecholamine systems that innervate these...
circuits, in the pathophysiology of ADHD. The prefrontal cortex and the striatum are part of a complex neural system that mediates inhibitory control processes. The prefrontal cortex receives higher-order sensory input and inhibits the processing of irrelevant sensory stimuli through reciprocal connections with temporal and parietal association cortices. In turn, the prefrontal cortex exerts inhibitory control over motor functions through well-organized connections with the caudate nucleus, and indirectly with the globus pallidus, which feeds back to the prefrontal cortex via thalamic nuclei.

Morphological studies using magnetic resonance imaging (MRI) in children and adolescents have generally found that cortical size is reduced in ADHD, as is the volume of several key structures, including the four major cortical lobes (frontal, parietal, occipital, and temporal) and the subcortical nuclei (e.g., putamen, caudate). These findings provide evidence that anomalies in the prefrontal cortex and basal ganglia (i.e., fewer prefrontal-corticostriatal fibers and less striatal feedback to prefrontal regions) may be uniquely associated with ADHD (Castellanos et al. 2002). The finding of reduced volume in the anterior genu region of the corpus callosum in children with ADHD is consistent with this hypothesis. Volumetric differences between ADHD and non-ADHD children in other brain areas, such as cerebellum, hippocampus and amygdala, further suggest that brain anomalies in ADHD extend beyond the prefrontal cortex and striatum to the posterior and subcortical regions that communicate with these frontal circuits. The regions most consistently found to be smaller in children with ADHD have been the dorsolateral prefrontal cortex, caudate, pallidum, corpus callosum, and cerebellum (Seidman et al. 2005).

An emerging literature has examined the developmental trajectory of regional brain volume in ADHD. Findings thus far indicate that volumetric differences in most regions remain parallel for ADHD patients and controls during childhood and adolescence. However, there are notable exceptions. The relative decrease in volume of caudate and putamen which is seen in children with ADHD does not seem to persist into adolescence—perhaps reflecting the relative decrease in observed hyperactive/impulsive symptoms developmentally (Castellanos et al. 2002). Similarly, decreased cortical thinning of the right parietal region over normal development was associated with more favorable outcome in 222 youth with ADHD who were positive for the DRD4 7-repeat allele (Shaw, Gornick et al. 2007). Combining genetic and neuroimaging methods offers an opportunity to better understand the neurodevelopmental effects of genetic polymorphisms, and by extension, neurobiological mechanisms related to variability in ADHD pathophysiology.

Several recent studies have examined whether relative differences in brain morphology are influenced by prior stimulant treatment—since many of the subjects in initial studies were previously medicated. The majority of findings support the view that genetic and/or early environmental influences on brain development in ADHD are relatively nonprogressive and unrelated to prior stimulant treatment (Castellanos et al. 2002). However, one study did find that the volume of brain structures implicated in ADHD (e.g., caudate, anterior cingulate cortex) differed as a function of preexisting treatment history (Semrud-Clikeman et al. 2006).

Neuroimaging studies investigating receptor density and binding properties using single photon emission computed tomography (SPECT), positron emission tomography (PET), or regional brain activation associated with information processing (i.e., functional MR imaging [fMRI]) have yielded important information regarding the pathophysiology of ADHD and mechanisms of action of medication treatments. Results of one series of studies documented the increase in extracellular DA following administration of clinical doses of MPH (Volkow et al. 2005), presumably providing a link to the mechanism of stimulant action. More controversial has been whether there is increased density of DA transporters (DAT) in ADHD, which could account for the hypothesized hypo-dopaminergic state in this disorder. Several studies have reported increased density of striatal DAT in adults with ADHD (Spencer et al. 2007a), but others have not found this to be the case (Volkow et al. 2007). Nevertheless, the inverse linear relationship between density of DAT and self-reports of inattention in both ADHD subjects and controls in the latter study suggests that, whether or not DAT density accounts for the hypo-dopaminergic state in ADHD, functionally decreasing DAT via treatment with stimulants (which bind to DAT) should improve attention.

More recent studies employing fMRI have examined the level of activation of prefrontal–striatal–thalamic regions (i.e., increased blood flow, generally taken to reflect use of the region) in subjects with ADHD in association with performance on inhibitory control tasks. Results of most studies have documented reduced striatal and increased prefrontal activation during response inhibition tasks, but there have also been contradictory findings. In addition, differences in activation extend to a variety of other regions. For example, in comparison with non-ADHD controls, adolescents with ADHD were found to have significantly greater activation of the left anterior cingulate cortex, right ventrolateral prefrontal cortex, and left basal ganglia during the dual task of interference control and response competition (Schulz et al. 2005). The notion that ADHD and non-ADHD youth process information differently is attractive, and potentially lines up well with the proposed neurobiological basis of ADHD. However, differences in group activation across studies could also reflect variability in task demands and corresponding differences in performance.

There have been fewer morphological and functional imaging studies of CD. Neuroanatomical investigation of children with ADHD alone and ADHD with comorbid CD found that morphological findings in cerebellum which have previously been reported in ADHD samples (i.e., smaller volumes of the left and total posterior superior and inferior lobes of the vermis) are present whether or not CD is also present. Morphological findings more specifically linked to CD include significantly reduced right temporal lobe and right temporal gray matter volumes, and possible reduced prefrontal volume (Kruesi et al. 2004). Findings from fMRI studies suggest differences in both cortical/executive and limbic function in adolescents with CD, as indicated by reduced activation in both anterior cingulate cortex and amygdala (Stadler et al. 2007). These findings could reflect impairment in both the recognition and cognitive control of emotional stimuli in patients with CD, which presumably might be associated with an increased propensity for aggressive behavior.
A more extensive literature has examined the neurochemical basis of CD, with particular emphasis on the role of NE and serotonin (5-HT). Reduced noradrenergic function in children with CD is suggested by findings of low cerebrospinal fluid (CSF) concentration of methoxyhydroxyphenylglycol (MHPG) (metabolite of NE) and reduced activity of the enzyme dopamine-β-hydroxylase (which converts DA to NA), possibly reflecting the role of NE in mediating behavioral arousal. Other research has examined the role of central serotonergic (5-HT) function in aggression and antisocial behavior, since antisocial adults have consistently been characterized as having a hypo-serotonergic state—as indicated by reduced CSF levels of 5-HT metabolites and reduced prolactin response to the 5-HT releaser/reuptake blocker fenfluramine. In contrast, the hypothesized inverse relationship between 5-HT and aggression has been less clearly demonstrated in studies in children. While the reasons for this are unclear, it is well known that aggression is more common in children than adults, and only about half of aggressive children continue to be aggressive over time. It would therefore seem unlikely that a single biological mechanism could explain the entire phenomenon. Consequently, one series of studies examined cross-sectional and longitudinal characteristics of aggressive children divided according to the level of central 5-HT responsivity in childhood. Those with reduced central 5-HT function were found to have numerous risk factors for persistence of aggression. Further, lower 5-HT responsivity in childhood predicted aggression in adolescence, adding variance above and beyond that accounted for by childhood aggression (Halperin et al. 2006). Finally, children with decreased 5-HT were more likely to develop ASPD in young adulthood (Flory et al. 2007). Interestingly, children with low 5-HT responsivity were quite sensitive to environmental events normally associated with CD, while those with high 5-HT responsivity were relatively protected. This suggests that 5-HT functioning may be a necessary but not sufficient condition for the persistence and escalation of aggression in youth, as high levels of psychosocial risk are also required. These findings highlight the importance of considering interactions among environmental and biological risk factors in the etiology of CD.

**Psychological Factors**

Neuropsychological models of ADHD have often focused on the primacy of executive dysfunction, as suggested by deficiencies in higher order cognitive functions such as inhibitory control, planning, working memory, and shifting sets. This model has been supported by a convergence of evidence from numerous studies examining neuropsychological test performance in both children and adults with ADHD compared to controls, results of neuroimaging studies indicating differences in structure and/or function in key fronto-striatal brain regions implicated in attention and self-regulatory function, and findings linking mechanisms of action of stimulant medications to many of these same regions. However, the results of several recent studies pose significant challenges for this model, including: (1) inconsistent findings in studies examining performance on specific neuropsychological tests of executive function in ADHD probands and controls; (2) results of large meta-analytic studies indicating that although groups of children with ADHD perform more poorly than controls on a wide array of executive function measures, the effect sizes for the various measures are low, particularly after controlling for potentially confounding variables such as intelligence, academic achievement and comorbidity; and (3) findings from studies in individuals with ADHD and controls which indicate that although executive function deficits are higher in individuals with ADHD than controls, only about half of the subjects with ADHD have executive function deficits. Further, it has been observed that the time course for neurodevelopment of the frontal lobe, which is ongoing throughout childhood and adolescence and is not complete until early adulthood, does not match the developmental course of ADHD, which begins in early childhood in the majority of cases, and is characterized by a decline in hyperactivity but less consistent decreases in inattention and cognitive impairment over time. This led to the speculation that neurodevelopment of the frontal lobe and associated functions might be associated with improvement in ADHD symptoms rather than the etiology of the disorder (Halperin and Schulz, 2006).

Taken together, the relatively high rates of executive dysfunction in ADHD and the above documented heterogeneity in this domain suggest that multiple pathways may be implicated. In addition to executive dysfunction, proposed the core deficits include cognitive-energetic factors, faulty time perception and delay aversion. The latter model is consistent with the observations that individuals with ADHD are attracted to stimulation and are very sensitive to reward, and suggest an alternative model of ADHD implicating ventral striatal reward circuitry (Sonuga-Barke 2005). Reward sensitivity is also prominent in youth with CD and substance abuse, conditions which frequently co-occur with ADHD. Models of ADHD that incorporate the construct of reward sensitivity are also consistent with findings supporting the efficacy of contingency management treatment approaches (Pflüger et al. 2000).

The cognitive-energetic model (Sergeant 2005) of ADHD is based on the observation that some individuals with the disorder have a slow and variable response style—perhaps reflecting impairment in cognitive mechanisms related to arousal and alertness, resulting in an apparent lack of preparedness to receive information and respond. This model is attractive for understanding individuals with predominantly inattentive subtype, who have often been described as having a sluggish demeanor and cognitive tempo. In addition, it is consistent with findings from neuropsychological research which indicate that individuals with ADHD have difficulty maintaining readiness to respond, and perform better on tasks where there is a shorter interval between stimuli.

**Social/Environmental Factors**

A variety of social/environmental factors are known to increase risk for ADHD and CD. Results of several studies have found that maternal use of alcohol, nicotine, cocaine and other drugs of abuse during pregnancy substantially increase risk for ADHD and conduct problems in offspring, possibly related to toxic effects on neurodevelopment of catecholamine systems and/or alterations in gene expression. The clinical presentation of children with fetal alcohol syndrome, including hyperactivity, complex learning problems (e.g., attentional problems, mixed expressive/receptive language and mathematics disorders), and/or disruptive
behavior is consistent with this hypothesis. However, interpretation of findings is complicated by the fact that rates of ADHD, substance abuse and conduct/antisocial disorders are likely increased in mothers who use alcohol, nicotine or other drugs during pregnancy, especially given the high degree of publicity regarding the potential deleterious effects of these behaviors. Thus, gene-environment interactions are likely involved.

A variety of other environmental risk factors have also been implicated in the etiology of the AD-DBDs. Exposure to high levels of lead increases risk for ADHD and other cognitive and behavioral problems, with recent findings indicating that even moderately elevated plasma levels may be associated with elevated risk. Other studies have focused on the possibility that exposure to environmental toxins, such as PCBs and mercury, can increase risk for ADHD (for review: Williams and Ross 2007).

Numerous social–familial factors have been shown to increase risk for the AD-DBDs. For example, shared family, peer and neighborhood risk factors have been implicated in the etiology of ODD and CD, and to a lesser degree ADHD. These so-called adversity factors include large sibships, parental separation, single parent households, child neglect, parental conflict, and poverty. Compromised child-rearing practices such as harsh physical discipline and poor supervision are also associated with elevated risk for ODD and CD. The most salient familial risk factor for CD is parental criminality, which likely has both environmental and genetic components. Delinquent peer membership and repeated victimization by peers also contribute to the development of CD and aggression, as does residing in a neighborhood with high rates of crime, poverty, and/or unemployment is associated with an earlier onset of CD. Recent data indicate that the experience of abuse, family violence or other traumatic events in early childhood may also be associated with increased risk for attentional and conduct problems. The above factors seem to operate in an additive fashion, with the probability of CD increasing linearly when there is aggregation of risk. Of note, these same psychosocial adversity factors increase risk for ADHD and ODD. Finally, a multitude of less serious but problematic parent-child interactions may influence the development and course of oppositional and disruptive behavior. Consistent with this observation, reductions in negative and ineffective parenting practices at home were shown to mediate improvement in children’s social skills at school in children with ADHD, combined subtype. However, improvement in the child’s behavior was only achieved when changes in parenting practices were fairly robust.

Treatment

Treatment Goals
Treatment of the AD-DBDs requires consideration of not only the core symptomatology, but also the full extent of cognitive, social, and psychological impairments that are often present. Given the wide-ranging nature of disruptive behavior, the high rates of comorbidity, and the presence of associated features such as academic underachievement, poor peer relations, and low self-esteem, multimodal treatments (i.e., psychopharmacological and psychosocial) are often warranted. It is very important to undertake psychoeducational efforts to instruct the patient and family regarding the nature of symptoms and the many ways they can affect individuals at home, work, school, and other areas of life. It is also important to assist families in finding and accessing available support services and related resources, and assist them in implementing accommodations as required across settings.

In initiating psychosocial and/or medication therapy, it is important to identify specific target behaviors associated with impairment in one or more settings, and to systematically assess change in the number and severity of these behaviors. In addition, it is important to assess comorbidity at baseline and over the course of treatment. In some instances, good response can be achieved with unimodal treatment (e.g., medication treatment for uncomplicated ADHD or ADHD + ODD; psychosocial treatment for ADHD + anxiety disorders, or behavioral intervention in ODD without other comorbidity). However, the presence of more severe conduct problems often requires combination treatment. As there are no specific medication treatments for ODD and CD, it is important to evaluate and identify comorbid disorders responsive to medication.

Somatic Treatments

Psychopharmacological treatment of the AD-DBDs can be traced to 1937, when benzedrine was first noted to produce behavioral improvement in a heterogeneous group of post-encephalitic children. Over the ensuing 70 years, there have been literally thousands of publications and several hundred controlled clinical trials on the effects of psychostimulant treatment, making it the best studied and validated medication treatment in child and adolescent psychiatry. Stimulants are the most frequently prescribed psychotropic medications in children, with prescription rates of 10–12% or higher in school age boys. There is also an US Food and Drug Administration (FDA)-approved nonstimulant, atomoxetine, and several other nonstimulant medications have been used “off-label” (e.g., bupropion, alpha-2 adrenergic agonists, modafinil and venlafaxine) because of known noradrenergic effects. Pharmacotherapy of ODD and CD is less solidly evidence-based, although findings from recent studies suggest that ODD symptoms in youth with comorbid ADHD + ODD are reasonably well treated using approved medications for ADHD. Treatment of CD is more complex, with many available medications used off-label, none of which can be recommended as fully evidence-based.

Psychostimulants

Psychostimulant Efficacy
Stimulants remain the most effective first-line treatment in uncomplicated ADHD, and have demonstrated effects in reducing disruptive behavior above and beyond their effects in ADHD. The majority of studies with stimulants have been conducted in school age children, and mostly boys. However, there are now ample data indicating that stimulants are effective in both males and females with ADHD across the lifespan, with efficacy of both MPH and amphetamine demonstrated in controlled trials in girls, and in mixed populations of adolescents and adults.

Literature reviews linked to the establishment of professional guidelines rate the evidence-base for acute stimulant treatment to be quite strong, for example, American
Academy of Pediatrics (2001); effect sizes for the core ADHD symptoms (i.e., inattention, hyperactivity and impaired self-regulatory capacity) in children and adolescents generally range from 0.8–1.0.

There are also treatment-related improvements in a variety of associated features and functional domains—including oppositionality, behavioral noncompliance, impulsive aggression, peer interactions, family dynamics, and ratings of self-esteem. Ensuring that the positive effects of treatment extend to these domains is essential to optimizing response. Improvement in academic productivity and accuracy has also been demonstrated, however, the hypothesized change in long-term academic achievement with treatment has been more difficult to substantiate.

**Psychostimulant Classes and Formulations**

There are several different stimulant formulations, divided among the two major classes, MPH and amphetamine (AMP), including immediate and extended release formulations and branded and generic products. Because stimulants have a short pharmacodynamic half-life and never functionally reach steady state, the medication has to be delivered relatively continuously over the course of the day. This is accomplished via administration of immediate-release formulations multiple times daily, or via extended duration formulations designed to replicate the pharmacokinetics of multiple daily dosing. Extended duration stimulant formulations are easy to use, decrease the potential for stigma associated with administration of medication during the school day, and presumably increase adherence to treatment. Consequently, treatment with long-acting stimulants has become the first-line approach.

MPH and AMP are both three dimensional molecules with d and l stereoisomers. Most MPH formulations contain the racemic form, but there are also immediate-release and extended-release forms of d-MPH, which is the active stereoisomer. There are now many long-acting formulations of d,l-MPH, with activity generally ranging from 8–12 hr. The original formulation, MPH-SR, embedded the active medication in a wax matrix, which produced extended duration but generally less robust response than immediate release formulations. The various second generation extended-release MPH formulations have different mechanisms of action. Several of these (e.g., d,l-MPH-CD, d,l-MPH-LA, d-MPH-XR) are double pulse formulations, which mimic twice daily administration of immediate-release MPH. In contrast, OROS-MPH uses an osmotically-controlled delivery system to produce constant and gradually increasing plasma levels over the course of the day. There is also a transdermal d,l-MPH formulation, with duration of action extending until approximately 3 hr after the patch is removed, potentially up to 15 hours. Together, the different MPH formulations represent the most often prescribed medications for ADHD.

The AMP class of stimulants includes both dextroamphetamine (DEX) and mixed amphetamine salts (MAS). The latter is a mixture of several amphetamine compounds, 75% of which is DEX. MAS-XR, a double pulse version of MAS, is the most frequently prescribed single medication for ADHD. A pro-drug formulation of DEX, lisdexamfetamine (LDX), covalently binds DEX to the amino acid l-lysine—rendering it inactive until it is metabolized in the gastrointestinal system. Release of DEX is more gradual when controlled through this metabolic pathway, and associated with decreased reports of euphoria and substance abusers. Intravenous or other nonoral routes of administration do not alter the kinetics of drug administration, also decreasing risk for abuse. Also, the duration of action of LDX is much longer than for other formulations of DEX.

Determining which stimulant class and formulation is best for the individual patient will often depend on judgments regarding the nature of impairment, duration of required coverage, and variability in individual response. Despite slight differences in mechanism of action, profiles of response and AEs, the different stimulant classes and formulations are relatively comparable in clinical efficacy and tolerability at the group level (James et al. 2001). However, there are frequently individual differences in response and/or tolerability. While most patients will respond to both MPH and AMP, certain individuals have selectively better response or tolerability with one or the other. Preferential response can be reflected in sensitivity to dose as well as adequacy of response. It is therefore important to begin treatment using a low dose, regardless of whether the patient has previously been treated with a different stimulant class. Relative differences in response and tolerability within a class are smaller, but there may be individual preferences for one or another formulation based on perceived efficacy and/or tolerability, duration of action or mode of delivery. These data underscore the importance of trying different medications if symptom management or tolerability is suboptimal.

In addition to selecting the best medication for the individual patient, it is important to consider individual differences related to both need for coverage (i.e., tasks that are best undertaken while medication is active) and duration of medication response. Since unregulated ADHD symptoms produce impairments in psychological, social and academic/vocational, and other functional domains, it is often important to maintain symptom control throughout the day. The inconvenience associated with multiple dosing with immediate release stimulants has been considerably improved through the development of effective extended-duration formulations. However, because symptom management is often required for longer than any of these medications remain effective, particularly in adults, and because the nature and severity of symptoms often differs over the course of the day, extended-release and immediate-release formulations are often used together. Formulations with longer activity than those currently available are currently being investigated in clinical trials.

**Stimulant Adverse Effects**

The most common AEs of stimulants are headache, abdominal pain, decreased appetite (with or without weight loss), and initial insomnia. There are slight increases in pulse and BP, which are not very meaningful at the group level but may be important in some individuals, particularly adults. Affective changes, including blunted affect, irritability, and mood lability can also be seen, either at peak dose or when the dose wears off. Use of longer acting stimulants tends to minimize mood lability and other AEs that are often considered to reflect the “on-off effects” which may occur with IR preparations. Despite initial concerns that motor or vocal tics can develop or be exacerbated, a convergence of evidence indicates that stimulant treatment does not necessarily
exacerbate tics and can be used safely in many cases. However, it is important to obtain a history of tic behaviors and examine the patient for tics, both prior to initiating medication and periodically over the course of treatment.

It is also important to monitor height and weight, and obtain a family history of growth in children treated with stimulants, as decreases in weight and growth attainment have long been recognized. Findings from initial studies indicated that slowing of growth occurs early in treatment, but then stabilizes and catches up over time. However, the MTA found that acute use of immediate-release stimulants, administered 3 times daily, 7 days per week, produced a slowing of growth by approximately 1 cm per year over the first 24 months of treatment in medication treated versus un-medicated subjects. Although the decrease in growth trajectory flattened after the initial treatment period, it did not “catch up” to the curve for the unmedicated group by 36 months (Swanson et al. 2007). Interpretation of these data are complicated by the fact that the ADHD children in this and most other clinical trials were larger than age and gender-based norms, so it is not clear whether this degree of slowing of growth is actually a concern. In addition, the overwhelming majority of subjects in this study received immediate release stimulants. Results from industry-funded trials with newer extended release formulations have generally found less flattening of the growth curve. While there is some lingering question as to whether flattening of growth trajectory is more problematic with AMP than MPH it is not a problem for the majority of stimulant-treated youth, regardless of medication class.

The relationship of stimulant treatment to cardiovascular risk was carefully reviewed after post-marketing surveillance identified 12 cases of sudden cardiac death in children taking MAS. However, approximately half of the reports were in patients with underlying structural heart defects; several others had other complicating circumstances, including use of additional medications, and others still had a positive family history of sudden death or other acute cardiac events. Given these findings, and considering that the risk for sudden death in patients taking stimulants does not exceed the base rate in the general population (0.6-6/100,000 per year) (Wilens et al. 2006), the FDA issued a warning for cardiovascular risk, but not a black box (www.fda.gov/cder/drug/infopage/ADHD). Prior to initiating stimulant treatment, it is essential to screen for a history of obstructive cardiac problems or a family history of early cardiac disease or death. However, it is not essential to obtain routine electrocardiograms (ECGs), since even a normal ECG does not guarantee the absence of a structural cardiac defect. Obtaining an echocardiogram and expert medical consultation should be considered in patients with arrhythmias, hypertension, structural cardiac defects, or a family history of untoward cardiac events.

A final safety consideration relates to the potential for stimulant misuse, abuse and diversion. Longitudinal data indicate that up to 11% of youth with ADHD report selling their medications, and 22% of those with comorbid CD or SUD reported misusing their medications (Wilens et al. 2006). College students are a population at particular risk, based on findings from several self-report surveys. It is therefore important to directly discuss issues related to abuse and diversion with adolescents and young adults, as well as parents of younger children, and to screen for signs and symptoms of substance abuse in monitoring treatment. Stimulant abuse and dependence generally occur in the context of other addiction disorders, and it is unlikely that patients will abuse their stimulant medication if other substance abuse is not also present. There are apparently not differences in the extent to which MPH and AMP are abusable, based on studies of mechanisms of action in humans and primates; both medications are associated with self-administration behavior in animals and produce subjective effects in humans associated with drug reinforcement or reward (i.e., wanting to use it again).

**Atomoxetine (ATX)**

ATX is the only FDA-approved nonstimulant medication for ADHD, and it is labeled for use in both children and adults. It is a highly selective norepinephrine reuptake inhibitor that is structurally distinct from both the stimulants and the tricyclic antidepressants. ATX increases synaptic norepinephrine (NE) in multiple brain regions, and dopamine (DA) levels in prefrontal cortex (Bymaster et al. 2002). ATX has low potential for abuse because it does not bind to receptors (i.e., dopamine, gamma-aminobutyric acid, opioid) associated with abuse potential, and does not increase DA in the striatum or nucleus accumbens.

Numerous controlled trials have demonstrated that ATX is effective in managing the core ADHD symptoms, with apparently equivalent response in inattentive and hyperactive–impulsive domains. Effect sizes for the core ADHD symptoms are in the medium to large range, somewhat lower than for stimulants at the group level. Treatment is associated with a reduction in impairment across several domains of function, including positive parental reports of child self-esteem, as well as social and family function in acute trials. Longer-term treatment was associated with improvement in learning and academic function in one study.

ATX is dosed on a weight-based schedule—with the target dose being 1.2 mg/kg. The precise duration of action is not known, however, the medication is effective whether administered once or twice daily, despite the fact that the half life in the large majority of people is 4–5 hr. ATX is metabolized via the cytochrome P (CYP) 2D6 system; 7% of individuals have a genetic polymorphism which makes them poor metabolizers. In these individuals, the half life of ATX is approximately 19 hr, and blood medication levels are much higher for any given dose. However, it is not necessary to determine CYP2D6 genotype prior to treatment, as studies using blind titration in slow and extensive metabolizers found that end of titration doses were nearly equivalent. Nonetheless, there is some suggestion that poor metabolizers have slightly better efficacy and slightly higher rates of AEs. ATX administration does not affect the pharmacokinetic properties of concomitant medications metabolized via CYP2D6 substrates. However, medications that alter CYP2D6 function, such as the fluoxetine and paroxetine, affect the metabolism of ATX—essentially converting many individuals from being extensive to poor metabolizers.

ATX has generally been well tolerated in clinical trials, with measured safety and tolerability data now extending to 5 years. The most commonly occurring AEs include sedation, nausea and vomiting, decreased appetite, weight loss, and increase in pulse and blood pressure (comparable
to stimulants). Irritability and increased aggression can also be seen, particularly in individuals with comorbid mood or behavioral syndromes. Longitudinal data indicate that effects on growth trajectory are relatively small in comparison to national norms, particularly after accounting for the initial effects of decreased appetite (Spencer et al. 2005). There is no specific risk for cardiovascular AEs or changes in ECG. However use of ATX is cautioned in patients with hypertension, tachycardia, or a history of cardiovascular or cerebrovascular disease, because it can increase blood pressure and heart rate.

There are two FDA warnings in effect for ATX—for liver toxicity and suicidal ideation. In 2004, post-marketing surveillance identified 2 cases (out of approximately 2 million exposures) of acute hepatotoxicity, although no cases have subsequently been reported. In both instances, patients had abdominal pain, jaundice, and substantially elevated liver function tests, which resolved with medication discontinuation. Obtaining routine liver function tests before initiating ATX treatment is not recommended, due to the very low frequency of liver toxicity, the fact that it cannot be predicted from baseline laboratory indices, and the clear presence of symptoms when it occurred. However, in patients at risk, or in those who develop abdominal pain or jaundice in association with treatment, a thorough work-up is indicated.

The FDA review of suicidal behavior in children treated with ATX was part of a larger investigation of suicidal behavior in youth treated with anti-depressant medications, since ATX shares a common mechanism of action (i.e., NE reuptake inhibition) with known anti-depressants (e.g., desipramine). Premarketing data were reviewed in 2200 children and adolescents from 12 short-term clinical trials (1357 treated with atomoxetine and 852 with placebo). There was a small but statistically significant increased rate of suicidal ideation—approximately 4 per 1,000 patients. Six cases were identified, and all were prepubertal children. Five of the six had ideation only, with uncertain intent. There was a nonlethal medication overdose in the 6th case. Consequently, there is a “black box” warning for suicidal ideation in the first few months of treatment (see FDA Web site: www.fda.gov/cder/drug/advisory/atomoxetine.htm). In evaluating and following patients treated with ATX, it is important to obtain a careful history of mood problems and/or suicidal behavior prior to starting medication, to educate patients and families regarding the importance of reporting changes in mental status, and to re-examine patients frequently at the beginning of treatment. Particular attention should be given to the acute emotional changes, including increased sadness, tearfulness, irritability, anger, or euphoria. As with other treatments, it is also wise to review the manner in which medications are stored and administered, and the importance of keeping medications away from young children.

Bupropion

Bupropion is chemically unrelated to other known antidepressants. Multi-center studies in both children and adults (Wilens et al. 2005) with ADHD found that bupropion was effective, although less so than stimulants. Bupropion may be particularly useful in the treatment of comorbid ADHD + depression, since it is an approved anti-depressant in adults. In addition, because it is not a stimulant, it may be effective in treating comorbid ADHD + substance abuse. Bupropion has been found to reduce ADHD symptoms in trials of adolescents and adults with ADHD and comorbid substance abuse (with several different substances studied), often in the context of other comorbid disorders (i.e., CD, depression). In addition, it has been shown to decrease craving and/or abuse in some of these studies.

Other

The noradrenergic tricyclic antidepressants, principally imipramine and desipramine, have been the most extensively studied and, until the mid-1990s, were the most often prescribed nonstimulant medications for ADHD. However, these medications are now infrequently used in children due to cardiac AEs. Tachycardia and postural hypotension are commonly seen, but are not often problematic. Prolongation of the PR and QT intervals may be a greater source of concern, so the premedication work-up should include an ECG. Prior to using tricyclics to treat children with ADHD, families should be informed that there have been several sudden deaths in children taking desipramine, although it has been argued that data from pharmacoepidemiologic studies and rates of sudden death in the general population do not support the conclusion that tricyclics have a high degree of cardiovascular toxicity in children.

There are preliminary data indicating that venlafaxine, a mixed serotonergic–noradrenergic reuptake inhibitor, might be useful for ADHD, based on reports of improved attention, concentration, and other cognitive functions in adults and children. The most commonly reported side effects are nausea and sedation, but light-headiness and changes in cardiovascular indices can occur. Open study findings have suggested that venlafaxine monotherapy may be an effective treatment for adults with comorbid ADD and major depression. However, double-blind, placebo-controlled trials have not been conducted. Although no precise recommendations for dosing in ADHD can be offered, it should be noted that the noradrenergic effects of venlafaxine are not substantive unless relatively higher doses are used.

Monoamine oxidase inhibitors (i.e., MAOIs) are non-specific enhancers of monoamine neurotransmission, and the MAOI tranyctopromine was used successfully to treat a small group of children with ADHD, with effects found to be comparable to DEX. However, using MAOIs in children and adolescents is impractical, given the likelihood of dietary indiscretions and the availability of several approved and better studied off-label treatments.

Alpha2-Adrenergic Agonists

Since the mid-1980s, there has been considerable interest in the use of alpha2- adrenergic agonists in the treatment of ADHD and aggression. Behavioral over-arousal and aggression are common targets of treatment, with more uncertainty regarding their role for inattention. Initial research and clinical use was with clonidine, a mixed alpha-2 agent. However, clonidine is quite short-acting, and treatment may be limited by sedation. There have also been concerns regarding cardiovascular toxicity—particularly following the occurrence of three sudden deaths in youth treated with the combination of clonidine + MPH. Results of subsequent studies (e.g., Tourette’s Syndrome Study Group 2002) found that the treatments are each effective, and can be used
together safely, with no appreciable ECG changes and incremental improvement in symptoms.

More recent efforts have examined the potential role for guanfacine, initially in the treatment of youth with ADHD + tic disorders, and subsequently in youth with ADHD alone. Guanfacine is relatively selective for alpha-2A receptors, which play a major role in the regulation of attention (Arnsten 2006), and it has a longer half-life and duration of action than clonidine. The immediate release formulation of guanfacine generally requires 2–3 times daily dosing. Pilot studies have suggested reduction of inattentiveness as well as hyperactive–impulsive behaviors.

An extended release formulation of guanfacine was studied in youth with ADHD, and received an approvable letter from the FDA in June, 2007. Findings from a double-blind, fixed-dose, multicenter trial in children and adolescents receiving 1 to 4 mg per day of guanfacine extended release or placebo, found significant reduction in ratings of ADHD symptoms in all dose groups. Adverse effects included dizziness, fatigue, headache, irritability, nausea, sedation, somnolence, and upper abdominal pain. A subsequent open-label, extension trial evaluated the long-term safety and efficacy up to 24 months, with good maintenance of therapeutic effect, good safety and reasonable tolerability.

Modafinil

Modafinil is a novel cognitive enhancer and wake-promoting agent, which is structurally and pharmacologically different from other agents used for the treatment of children with ADHD. It selectively activates cortex and modulates several different neurotransmitters, including hypocretin, histamine, norepinephrine, gamma-aminobutyric acid, and glutamate. Modafinil is FDA approved for the treatment of narcolepsy and shift work sleep disorder, as well as for adjunctive treatment of obstructive sleep apnea/hypopnea syndrome. It is a schedule 4 stimulant, with evidence suggesting only limited potential for large-scale abuse.

Several clinical trials evaluated the efficacy and tolerability of a new formulation of modafinil, as well as the effects of acute discontinuation (Swanson et al. 2006), with significant improvement in ratings of ADHD symptoms both at home and school. However, despite receiving an approvable letter from the FDA in 2005, the new formulation was ultimately not approved by the FDA, due to concerns that the occurrence of a skin rash in one subject could potentially indicate elevated risk for Stevens-Johnson syndrome. The relative absence of cardiovascular AEs suggests that modafinil could be useful for treating selected adults with ADHD, and possibly older children, provided they are nonresponders or nontolerators of approved medication treatments.

Serotonin Reuptake Inhibitors

There are several open studies and case reports using fluoxetine, a selective serotonin reuptake inhibitor (SSRI), in the treatment of children with AD-DBDs—both with and without comorbid mood disorder. The rationale for this approach is linked to results of studies in adults implicating serotonergic mechanisms in aggression, and the successful use of fluoxetine in treating a subgroup of adults with impulsive aggression. The frequent co-occurrence of mood and anxiety disorders in youth with ADHD and CD suggests a possible role for the SSRIs. However, there have not been controlled studies of SSRI treatment of either ADHD or CD, and the potential role of SSRIs in treating comorbid ADHD/CD/Depression is inferential only.

Atypical Antipsychotics

Neuroleptic medications have been used for decades to treat children with severe behavioral problems characterized by aggression and combativeness. First generation antipsychotics such as Chlorpromazine, Thoridazine, and Haloperidol were FDA-approved for this indication, however, they are rarely used as primary treatments. More recent study has focused on the potential utility of the atypical neuroleptics. The best controlled data are for risperidone, with several controlled trials documenting utility in treating aggressive symptoms and even hyperactivity (Schur et al. 2003). Several of the above studies were conducted in individuals with developmental disabilities and/or subaverage IQ (for example, see Aman et al. 2005); others examined behavioral disturbance in the context of mood dysregulation. Open studies and case reports are available for several of the other atypical antipsychotic medications—most notably quetiapine. Additionally, there have been open reports with aripiprazole. The latter is of considerable interest because of the occurrence of metabolic syndromes following use of other atypical antipsychotics.

Mood and Behavior Stabilizing Medications

A variety of other pharmacotherapeutic agents have been utilized off label in the treatment of aggression and episodic dyscontrol, although efficacy in the treatment of CD has not been established. Studies with lithium have yielded mixed results. Positive results were reported in the well-controlled studies of aggressive children, impulsive-aggressive adolescents and young adult delinquents. However, the effect size in several more recent studies in children and adolescents was only modest. Further, concerns regarding potential AEs and the need to follow blood levels represent potential drawbacks for widespread use of lithium in children.

Several anti-epileptic medications have been investigated, again with mixed results, although there continues to be substantial off-label use in the treatment of aggression. The best data are for sodium valproate, which was shown to be effective in a controlled trial of adolescents with aggression, chronic temper outbursts, and mood lability (Donovan et al. 2000). Initial placebo-controlled data for carbamezapine in youth with aggressive CD were promising, but subsequent studies did not replicate the finding. Several of the newer antiepileptic medications used to treat mood and bipolar disorders may also be relevant for youth with CD—including topiramate and lamotrigine. The former is attractive because it does not result in the weight gain—unlike most other neuroleptic or anticonvulsant mood and behavior stabilizing medications. However, it can result in cognitive dulling, particularly at higher doses. Lamotrigine has been used to treat behavioral disturbance in the context of depressive/bipolar syndromes, however, it has been associated with risk for Stevens-Johnson syndrome, particularly in young children. There is an older literature with beta-adrenergic blockers such as propranolol in the treatment of aggression, primarily in children with mental retardation. However, controlled trial data are lacking.
Psychosocial Treatments

A variety of psychosocial therapies are useful for treating children with AD-DBDs. Systematically studied psychosocial interventions include home based interventions/parent training, classroom-based behavior modification, social skills training and intensive summer treatment programs (Wells et al. 2000). Since family, peer and school interactions are important in the morbidity and maintenance of these disorders, it is important to utilize psychosocial treatments to target each of these areas. Psychoeducational interventions are almost always indicated. In contrast to these more structured and symptom oriented approaches, individual play therapy with children is generally ineffective in decreasing symptoms of the AD-DBDs. However, there may be a role for this and other less structured therapies in treating problems related to adjustment, self-esteem, and comorbidity.

Psychoeducational intervention should begin at the time of diagnosis, as it helps patients/families understand the nature of the disorder and learn to restructure the environment to improve management of the condition. Helping families appreciate that the AD-DBDs have a substantive neurobiological basis can have positive effects in reducing negative global attributions and maintaining a positive sense of self-efficacy and self-esteem. Highlighting common impairments and teaching patients/families to anticipate them is also helpful. Also, it is important to counsel families regarding the range of aids and/or structural accommodations that are available and can be accessed.

Behavior therapy (BT) has been successfully utilized in the AD-DBDs, either alone or in combination with other interventions. Most behavioral approaches in involve working with parents and/or teachers as the agents of change. The focus is on decreasing the frequency of problematic behaviors and/or increasing the rate of desirable behaviors through the environmental manipulation and/or the contingency management techniques. Parent management training is one of the most common approaches, consisting of group and/or individual sessions which offer a combination of psycho-education, instruction in behavioral treatment approaches, and interventions which facilitate their implementation. Contingency management, in which rewards or privileges are earned for meeting stipulated desired or prosocial behaviors, and rewards are withheld or punishments applied for rule violations (Piffiner et al. 2000), is often used. Time-out may be utilized to remove the child from a negative situation or to interrupt certain undesired behaviors.

Use of contingency management in the children with AD-DBDs is linked to the observation that individuals with ADHD and disruptive behavior are highly sensitive to reward. Requirements for successful implementation are the clear elaboration of target behaviors, including the gains to be achieved in meeting behavioral expectations and the consequences of falling short. It is desirable that the child participate in some aspects of the treatment in order to understand how the behavioral plan will work, and to provide input into the selection of rewards. This is extremely important to engage the child and maintain motivation over time. It is essential that rewards reflect the individual values of the child and his/her milieu, and not be onerous for the parent in terms of cost or personal values. It is also important to appreciate the need to change rewards over the course of treatment, as the child’s perception of the reward changes or the child grows too familiar with it. While the frequent shifting of behavioral targets and/or rewards can be seen as an impediment to implementing BT, it is actually one of its major assets. The flexible nature of BT makes it possible to develop interventions that are tailored to the problems and needs of the child and family, to target specific tasks or settings, and to adapt the treatment to changing needs and/or impairments as they arise.

BT can be structured to incorporate tasks related to cognitive function, homework completion, social interactions, and a variety of other tasks or behaviors. Programs often target school behavior and performance via contingency management strategies implemented at home which support selected target outcomes at school. Consultation with teachers is often used to augment home-based interventions. School-based BT programs can be implemented by a variety of personnel, including classroom teachers, guidance counselors, teacher assistants and paraprofessional aids. When specific interventions or supplemental personnel are introduced to meet the needs of an individual child, it is important to do so in a manner that minimizes stigma. An alternative approach is to incorporate aspects of BT into overall classroom management strategies, or to utilize paraprofessionals to accomplish a broader range of behavioral objectives for the class, and not only those of the individual child.

A variety of psychosocial approaches can be used target problems with attention and other cognitive skills, self-perceptions, and social function—many of which are impaired in individuals with AD-DBDs. Cognitive–behavioral therapy (CBT) approaches are best reserved for older children, adolescents and adults, and can only be implemented when there is sufficient behavioral control. Cognitive–behavioral approaches are based on the premise that certain undesirable, thoughts, perceptions and behaviors are over-learned, and that a structured, symptom-focused intervention can help patients reframe how they think about or manage behavior, and to implement self-regulatory or other compensatory strategies. Examples of CBT include training in self-monitoring, anger control and self-reinforcement. CBT is theoretically well suited to helping patients manage problems with task engagement, completion and organization, and also to minimize secondary problems related to self-esteem, demoralization or anxiety. Specific interventions designed to improve attention and organizational skills in adolescents and adults with ADHD are currently being investigated, but are not yet widely available.

Social skills training is based on the recognition that symptoms of ADHD, ODD and CD often affect social function, and that many individuals with AD-DBDs have specific impairments in self-observation and/or reading social cues. Social skills training is best offered in a group setting which replicates the outside milieu as much as possible—since generalization of gains to other settings is difficult to achieve. To address this potential limitation, an intensive Summer Treatment Program (STP) has been developed (Pelham et al. 2000)—which offers social skills programming in combination with cognitive/educational remediation, using a variety of contingency management principles, and augmented by parent behavior management training—in the context of what is essentially a summer day camp. This approach is well suited to provide the requisite variety and intensity of...
behavioral interventions, in a setting that closely replicates normal school and summer programming, and in a manner that is engaging and enjoyable to children, supportive of family needs, and not stigmatizing.

**Comparing Response to Medication, Psychosocial and Combination Treatments**

The MTA compared 14 months of randomized treatment with medication, psychosocial treatment or the combination with each other and community standard treatment in 579, 7–10-year old, children with combined subtype ADHD. The medication arm consisted of algorithmically driven treatment with immediate release MPH given three times daily, followed by trials with DEX or other medications if these were not effective. The psychosocial arm consisted of a variety of interventions, including: an intense parent behavior management training program, ongoing consultation to the classroom teacher, a summer treatment program and a paraprofessional aid program (Wells et al. 2000). The 14 month intent-to-treat analyses indicated that, for ADHD symptoms, treatments that included medication performed better than other treatments (MTA Cooperative Group 1999a). This finding was replicated in a different two-site comparative medication–psychosocial trial using a similar but slightly different design (Abikoff et al. 2004). For non-ADHD symptoms in the MTA study, only combined treatment was statistically superior to community standard care. Combined treatment was not significantly different from medication only, but there was a small difference in effect size favoring the combined treatment in several different analyses. When the different variables from these analyses were incorporated into a single composite measure (i.e., defining a broader definition of response, and increasing statistical power) combined treatment was demonstrated to be superior to both unimodal treatments (Conners et al. 2001). Age, gender and comorbid CD/ODD did not moderate the primary intent to treat findings, however, behavioral treatment alone was more effective in children with comorbid ADHD and anxiety disorders than in those without anxiety disorders (MTA Cooperative Group 1999b).

Longitudinal follow-up of the MTA sample has yielded a complex pattern of results. The effect size favoring randomization to medication treatment was reduced by approximately 50% at 24 months posttreatment, 10 months after the active study treatment ended. By the 36 month assessment, there was no longer a significant advantage for the group originally randomized to medication (Jensen et al. 2007). Analyses using latent class modeling of response and grouping of subjects according to naturalistic treatment selection (i.e., the treatment chosen after the study ended) indicated that membership in the various response classes was mainly not determined by whether or not subjects were treated with medication. However, within several of the classes, there was modest benefit associated with medication treatment (Swanson et al. 2007). These findings suggest that the longitudinal course of ADHD may be predominantly accounted for by a multiplicity of constitutional and environmental factors, and not treatment per se. Seen in this context, the role of long-term treatment would be to modify the course within the limitations imposed by these various constitutional and environmental factors.

**Special Factors Influencing Treatment**

**Comorbidity**

Results of numerous studies indicate that the children with and without aggression respond equally well to stimulant treatment in reduction of ADHD symptoms. In addition, stimulant treatment can ameliorate conduct problems independent of its effect on ADHD. In the MTA study, comorbid ODD/CD did not moderate the beneficial effects of treatment on ADHD symptoms, however, response was superior when medication was used (MTA Cooperative Group 1999b). The best outcome in this comorbid group was seen with combined treatment (Jensen et al. 2001). The absence of moderator effects of comorbid ODD has been replicated with the new longer acting stimulant formulations, and has also been extended to atomoxetine.

Other research has examined whether comorbid LD moderates stimulant response, with the overall observation that cognitive measures associated with ADHD improve irrespective of LD. When LD is present remediation is often also required. Improvement in cognitive function is thought to follow a linear dose-response curve, however, there have been questions about whether this is equally true for the different ADHD subtypes (Stein et al. 2003), and whether there are deleterious effects on cognition if higher doses are used. One early study found that optimal cognitive performance was achieved with low dose DEX (i.e., 0.3 mg/kg). Optimal behavioral function was achieved with high dose (i.e., 1.0 mg/kg), but there was an associated decline in cognitive function. Findings from animal studies support the hypothesis that high doses of stimulants may be associated with decreased cognitive performance, however, most clinical trials have not found this to be so—either because the relative dosing of stimulants is lower in humans, and/or because it is difficult to distinguish cognitive inflexibility and perseveration from vigilance. A related issue is whether optimal dose varies as a function of comorbidity. Findings from studies with both stimulants (e.g., Spencer et al. 2006) and atomoxetine (Newcorn et al. 2005) do indicate that higher dosing is required in ADHD + ODD. An earlier study found that low dose MPH was sufficient for ADHD and either comorbid internalizing or externalizing disorders, but the combination required higher dose treatment.

Studies of stimulant response in children with ADHD children and comorbid anxiety have yielded inconsistent findings. Earlier investigations found stimulants to be effective in reducing ADHD symptoms in the comorbid group, though response was less robust and there was heightened sensitivity to AEs. However, more recent studies have found that stimulant medication is equally effective in ADHD youth with and without anxiety disorders (e.g., MTA Cooperative Group 1999a). Furthermore, stimulants do appear to not increase anxiety at the group level, and may reduce anxiety in some children (Abikoff et al. 2005), possibly due to a reduction in secondary anxiety following the expected improvements in performance associated with treatment of ADHD. Stimulant treatment did not significantly improve anxiety symptoms, but the study was not powered adequately to show this. Subsequent addition of fluoxetine treated anxiety successfully, and was generally tolerated well.

ATX may be particularly useful in the treatment of ADHD and several comorbid disorders, with the best data
thus far in comorbid anxiety and tic disorders. Children and adolescents with ADHD and anxiety disorders treated with ATX showed significant improvement in both ADHD (ES = 1.0) and anxiety symptoms (ES = 0.5) (Geller et al. 2007). Also, ATX did not worsen preexisting tics in subjects with ADHD + chronic motor tic disorders, and improvement in tic severity was seen in the subgroup of subjects with TS (Allen et al. 2005). Improvement in ODD symptoms in youth with ADHD + comorbid ODD has been more inconsistent, with findings varying across studies. However, as with stimulants, co-occurrence of ODD symptoms does not alter response of ADHD symptoms to ATX. Finally, there has been interest in whether ATX can be used to treat children with PDD spectrum disorders and ADHD symptoms. Findings from a small, randomized, crossover pilot study found that ATX significantly reduced hyperactive symptoms in this population with relatively good tolerability (Arnold et al. 2006).

Figure 46–1 Texas algorithm for the pharmacologic treatment of ADHD. (Source: Pliszka et al. (2006) Journal of the American Academy of Child and Adolescent Psychiatry 45(6), 642–657.)
Developmental Effects

Although ADHD had previously been primarily considered a disorder of school age children, an emerging literature has evaluated treatment response across the lifespan. There are now large studies in preschool children, adolescents, and adults with ADHD, all demonstrating positive effects. However, age-specific differences in response are also observed. For example, effect sizes of medication treatment were lower in a multi-site, multimodal treatment study in preschool children than in previous studies with school age children and adolescents (Greenhill et al. 2007). This may be due to the lower doses used in treatment, the requirement that intensive psychosocial treatment be given before medication and/or the greater severity of early onset cases. Effect sizes of approved treatments for ADHD (i.e., d-MPH-XR, d,l-AMP-XR, atomoxetine) are also lower in adults than they are in children—particularly at FDA-approved doses, which are lower for the two approved stimulant formulation in adults than in children. Also contributing to the lower effect size in adults is the fact that placebo effects increase along with the age of the sample—with somewhat larger placebo effects observed in adolescents compared to children, and even larger placebo effects in adults. Finally, the objectives and targets of both medication and psychosocial treatments vary considerably as a function of age, so differences in the nature and magnitude of response should not be surprising. For example, since adults have a higher proportion of inattention symptoms, and these are often difficult to observe directly (there is no analogue for teacher ratings in adults), information is most often obtained via self-report—potentially introducing greater susceptibility to expectancy bias.

Treatment Algorithms and Practice Guidelines

The fact that there are multiple available medications for the AD-DBDs, and no way to accurately predict who will respond optimally to one or the other, means that treatment is conducted empirically in sequential fashion. The goal of treatment is to normalize symptoms as best possible, without sacrificing tolerability and patient/family satisfaction. Incomplete responders or poor tolerators of any one medication class should have trials of additional treatments until...
the optimal medication and dose have been determined. Various medication guidelines or practice parameters have been developed to reinforce the use of evidence-based treatments, and to help guide treatment selection in various contexts. This is important because it is often difficult to translate findings from results in pristine clinical trials, conducted in carefully selected patients, to the complex and diagnostically heterogeneous populations more often encountered in real-world settings. These guidelines are generally derived from a composite of published research and expert opinion, and offer a clinical standard of care that practitioners can use to inform treatment selection and sequencing of treatments—often in the absence of a suitable evidence-base for several of the specific treatments. Guidelines for the treatment of ADHD include those from the American Academy of Pediatrics (2001) and the American Academy of Child and Adolescent Psychiatry (Piszka et al. 2007). Recommendations based on expert opinion have also been developed for ADHD (i.e., the Texas Medication Algorithm project (Piszka et al. 2006)) (see Figure 46–1) and aggression in youth (i.e., treatment recommendations for the use of antipsychotics for aggressive youth (TRAAY) (Schur et al. 2003, Pappadopulos et al. 2003)). Treatment algorithms for ADHD reflect the multitude of approved and nonapproved treatments, and the many different clinical presentations which may affect how these treatments are used—including the frequent occurrence of comorbidity. The most recent Texas Medication Algorithm project revisions included elimination of pemoline as a treatment option, based on severe liver toxicity, addition of atomoxetine to the algorithm, and refining guidelines for treating ADHD with comorbid depression, aggressive behaviors, and tic disorders (see Figure 46–1). The TRAAY recommendations (see Figure 46–2) primarily focus on the use of atypical antipsychotics, but also describe the various psychosocial and medication treatments and propose how they can be used sequentially.

In summary, treatment algorithms provide sensible, common starting points for treatment selection, and offer decision-trees that are flexible enough to be modified for the individual patient. However, they should be viewed as general guidelines for care rather than absolute rules. Further, frequent updates are required to reflect the rapidly changing evidence-base in the field.

Conclusions

The AD-DBDs are a group of disorders that represent a significant public health problem in terms of morbidity and cost to society, and carry substantial risk for poor outcome. Together they account for the majority of referrals to child and adolescent psychiatry services. In recent years, there has been an increasing recognition that symptoms of AD-DBDs often begin early in life and persist into adulthood. There has been considerable progress in elucidating the genetic and neurobiological bases of these disorders. A plethora of new medication treatments for ADHD have become available over the past decade, revolutionizing the way care is delivered. These and other medications have also been used effectively in treating ODD and CD. However, clinical treatment and research is complicated by the high prevalence of comorbidity, which has an important role in moderating clinical presentation, response to treatment and longitudinal course. A variety of pharmacological and psychosocial interventions have been found to be effective when administered alone or in combination over the short term. However, demonstrating long-term benefits of treatment continues to be a challenge.

Acknowledgments

The authors would like to thank Dr. Mariana Markella, for her assistance in the preparation and formatting of this manuscript and Dr Lenard Adler, for his inputs to the section on assessment of adults with ADHD.

Introduction

Feeding is an essential yet highly complex behavior. It requires the successful integration of a number of different aspects of development and function, which in turn are related to different bodily systems. In addition, infant feeding is dependent on a nurturing relationship with a caregiver. When one or more of the prerequisites for successful feeding (e.g., gut motility, swallow reflex, and appetite) are delayed, dysfunctional, disturbed or absent, significant problems may ensue. Gastrointestinal disorder, attachment problems in the relationship between mother and child, and structural abnormalities of the mouth or tongue can lead separately or together to the final common pathway of problems in feeding. Feeding disorders therefore straddle different professional boundaries and benefit from an integrated multidisciplinary approach to assessment and treatment (Rommel et al. 2003).

In view of the complexity of feeding behavior, and need for co-coordinated, integrated multiple system functioning, it is perhaps unsurprising that feeding problems are relatively common in infants and young children. Feeding problems can occur in children having normal development, those having developmental disability or disorder, and those suffering from a whole range of medical conditions. Such children can present to the clinician with one or more of different types of difficulty, the most common of which are summarized in Table 47–1. Some feeding problems may be relatively short lived and can be regarded as part of a

normal developmental trajectory, appropriately managed by information, advice, and reassurance. Others may be a direct result of oral motor dysfunction, gastrointestinal, or other medical conditions, and require investigation and first-line management by speech and language specialists or by pediatric physicians or surgeons. The remainder may be best understood as—or in the context of—behavioral, emotional, and relationship disturbances that are manifest as an inability, or unwillingness, to feed or eat normally, and it is this latter group that forms the focus of this chapter. A significant number of young children presenting with feeding disorders will have had early histories of problematic feeding, requiring medical intervention, but the condition is considered to have resolved sufficiently to allow normal feeding to place. While feeding disorders may come to the attention of a wide range of professionals, and may be appropriately treated and managed by representatives of other disciplines, the material included in this chapter has been selected with the specific intention of informing and guiding mental health professionals.

It may be helpful at this stage to refer briefly to the use of some key terms, in particular to the common distinction made between “feeding” and “eating.” Feeding generally denotes something that happens in the context of a relationship, whereas eating generally denotes an action of an individual. Feeding refers to what happens in the two-way relationship between the child and the carer, and in this sense it may be considered a relational process. Problem feeding can then be understood and managed in this context, which means that attention and input need to be provided to both the child and the caregiver. The term “eating” tends to be used in older children and individuals who self-feed and are more likely to make their own choices about dietary intake.

Davies et al. have called for a reconceptualization of feeding and feeding disorders within such an interpersonal context, pointing out that current diagnostic criteria (see below) are focused on the child as an individual (Davies et al. 2006). They suggest that this is illogical given the dyadic nature of the feeding relationship and have suggested revised criteria for a diagnosis of “feeding disorder between parent and child.” It could be argued that such a move might enhance the clinical utility of the diagnosis (Kendall and Jablensky 2003), in at least two important ways: through assisting clinicians in choosing effective interventions and in predicting future clinical management needs (see further First et al., 2004, for discussion of choosing clinical utility as a criterion for diagnostic revision).

This chapter is concerned with feeding and related problems in infants and young children that meet a number of conditions:

1. They are not fully accounted for at the time of presentation by an underlying medical problem, although such a problem may have contributed to the development of the feeding disorder.
2. They are clinically significant in terms of having an adverse effect on one or more areas of development (typically growth, but other areas such as social development may also be affected).

The three formally diagnosable disorders described in this chapter in detail are feeding disorder of infancy or early childhood, rumination disorder, and pica (American Psychiatric Association 2000).

### Feeding Disorder of Infancy or Early Childhood

**Definition and Diagnostic Features**

The main presenting feature of Feeding Disorder of Infancy or Early Childhood (307.59) is weight loss or failure to gain weight due to feeding disturbance. The current diagnostic criteria are not specific about the extent or severity of the weight loss or failure to gain weight, or about the origin or nature of the feeding disturbance. However, they are explicit that at the time of diagnosis it must not be directly due to a medical condition or more clearly accounted for by another mental disorder. Also, the criteria are explicit that the feeding problem must not be due to lack of food and that the weight loss or failure to gain weight must be at least of 1-month duration.

It should be noted that many children presenting to clinics because of problem feeding will not fulfill diagnostic criteria for feeding disorder despite significant, persistent feeding disturbance. For example, children who have become “stuck” on enteral feeding, despite there being no longer any medical reason for this, or children who eat only pureed foods, despite having no oropharyngeal difficulties, will tend not to meet the weight criterion. Such children have clear emotional and behavioral aspects to their presentation, and yet do not clearly fit any available diagnostic category. Keen diagnosticians can sometimes tuck them away in “not otherwise specified,” “other,” or “unspecified” categories of other disorders, for example, anxiety disorders, but this seems far from satisfactory. In addition, the term, “feeding disorder” when correctly applied includes children with a wide range of different features associated with the required failure to eat adequately and failure to gain weight or significant weight loss. Because of the many associated characteristics, there have been several attempts to find ways to subclassify feeding disorders to satisfactorily take account of the many different ways in which these children

---

**DSM-IV-TR Criteria**

**Feeding Disorder of Infancy or Early Childhood**

A. Feeding disturbance as manifested by persistent failure to eat adequately with significant failure to gain weight or significant loss of weight over at least 1 month.

B. The disturbance is not due to an associated gastrointestinal or other general medical condition (e.g., esophageal reflux).

C. The disturbance is not better accounted for by another mental disorder (e.g. rumination disorder) or by lack of available food.

D. The onset is before age 6 years.

present. Different researchers and authors have adopted different conceptual frameworks and approached subgrouping from different perspectives. This has resulted in inconsistent and idiosyncratic use of terminology with, as a consequence, limited scope for co-ordinated clinical and research endeavor. This remains a major challenge for the field. Some examples of attempts at subgrouping feeding disorders are set out below:

**Organic versus Nonorganic Origin**

Dividing feeding disorders into those with organic and nonorganic origin has been popular in the past, with many authors distinguishing between types of presentation on this basis (e.g., Weir 1979). Chattoor et al. have proposed criteria for subgroups of types of feeding disorders amongst children presenting with nonorganic failure to thrive, including “infantile anorexia” and “feeding disorder of mother–infant reciprocity” (previously called feeding disorder of attachment) (Chattoor et al. 1997). Making a distinction between organic and nonorganic presentations assumes that feeding disorders are either related to structural or functional abnormalities related to the mouth and gastrointestinal system or are triggered by social and environmental factors. This has been criticized because it is relatively rare to find a single cause to explain feeding disorders in children; it is most often the case that the feeding disorder appears to result from the combination and interaction of physical and psychosocial factors. In addition, the term “nonorganic” often seems to be made without rigorous assessment that might exclude any organic component. For example, Reilly et al. 1999 found that of 47 children with nonorganic failure to thrive, 36% had oral motor dysfunction; these authors concluded that the use of the term “nonorganic” in such children is questionable, and along with others have called for a redefinition (Ramsay et al. 1993).

**Biopsychosocial Approaches**

Because of difficulty with a dichotomous system, a number of authors have distinguished feeding disorders based on three or more groups of contributing factors.

The three areas most commonly documented as having an etiological contribution in children with feeding problems are structural or oral problems (e.g., oropharyngeal functional abnormality), medical problems (e.g., gastroesophageal reflux), and psychosocial or behavioral problems (e.g., aversion of lumps and relationship problems). For example, in one study of 700 children under the age of 10 with feeding disorders, 86% had an underlying medical disorder, 61% had some oropharyngeal dysfunction, and 18% had a behavioral problem (Rommel et al. 2003). These conditions occurred alone or in combination, which highlights the difficulty in assigning feeding difficulties to specific categories.

In response to the fact that categories appear not to be mutually exclusive and fail to adequately capture children with feeding disorders of mixed etiology, Burklow et al. (1998) identified five categories of feeding disorders, reflecting the types of referrals received by their multidisciplinary feeding team. They report satisfactory interrater reliability for this categorization (88%):

1. **structural abnormalities**—anatomic abnormalities associated with the physical structures required for eating;
2. **neurological conditions**—brain injury, learning disabilities, musculoskeletal disorders, and autistic spectrum disorders (ASD);
3. **behavioral and psychosocial**—poor environmental stimulation, dysfunctional child—caregiver interaction, negative feeding behaviors shaped by reinforcement and/or emotionally based difficulties;
4. **cardiorespiratory problems**—compromised cardiovascular and respiratory systems, complication coordination of sucking, swallowing, and breathing; and
5. **metabolic dysfunction**—metabolic diseases and syndromes that interfere with normal feeding patterns.

These authors categorized a series of 103 children referred because of concerns about poor oral intake and difficulties sustaining growth. Using the above categorization they reported the following as most frequently coded combinations: structural–neurological–behavioral (30%), neurological–behavioral (27%), behavioral (12%), structural–behavioral (9%), and structural–neurological (8%). Of interest is the reported 85% in whom behavioral issues were coded, compared to neurological conditions in 73% and structural abnormalities in 57%. A source of puzzlement is the lack of a category to cover gastroenterological conditions. Nevertheless, this study very clearly demonstrates that the majority of children with feeding disorders have a behavioral component to their presentation and that in the majority of patients, biological and behavioral components interact. The authors conclude that feeding problems are best conceptualized as biobehavioral conditions (Burklow et al. 1998).

**Subgrouping Based on Presenting Characteristics of the Feeding Problem**

Crist and Napier-Phillips (2001) provide an example of an attempt to subdivide on the basis of presenting behavioral features. They used a measure of feeding behavior devised by their group (the Behavioral Pediatrics Feeding Assessment Scale — see later section on assessment) in a clinical series of 249 children with feeding problems with and without related medical issues, and in 96 control children. They subsequently conducted a factor analysis of data obtained and identified five common patterns of problematic feeding behavior: picky eating, general toddler refusal, toddler refusal of textured foods, general refusal in older children and stalling. Interestingly, they found that the difference between the clinical and the control groups appeared to lie in parental report of the frequency with which the child engages in the problematic behavior, rather than differences in the nature of the behaviors exhibited.

**Subgrouping Based on Presence or Absence of Mental or Developmental Disability**

Some authors make a distinction between children with feeding disorder who are on the autistic spectrum or have significant learning disability and those who do not. Often the presenting features of the feeding problem can be the same (e.g., unwillingness to take solids, or a very narrow range of accepted foods) but the treatment approach may differ considerably. However, as with feeding disorders in children with no developmental disability or disorder, there can be a significant medical component to the presentation. Schwartz et al. 2001 report the results of diagnostic
Clinical Vignette 1

Food Selectivity in a 6-Year-Old Boy with Childhood Autism

Chris is a 6-year-old boy who was diagnosed with childhood autism at the age of 4. His local pediatrician referred him to a feeding clinic because of his very restricted diet. Chris was breast-fed for 6 weeks and moved onto bottle feeding with no problems. He was introduced to purees at 5 months and this went well. When parents attempted to introduce more lumpy foods Chris would vomit. His progress with feeding was delayed and he progressed to mashed food at age 3. At age 4, risks (in the UK, risks are biscuits given to infants, sometimes soaked in milk and mashed up) were introduced, but by age 5 he had no range of foods narrowed and he would only accept pureed fruits, oatmeal cereal, and cow’s milk. Chris’s parents then reintroduced an infant formula feed, as they were concerned about the nutritional inadequacy of his diet. He would only accept milk from a bottle with a nipple.

At presentation, Chris was accepting only toast, yogurts, crispbread, a particular type of savory snack, and infant formula from a bottle. His diet was more than sufficient in terms of calories, and he presented as slightly overweight; however, it was lacking in a number of essential vitamins and minerals. His presentation was typical of a selective eater on the autistic spectrum in that he chose to eat foods from a limited range of food groups (mainly, carbohydrate and dairy). His chosen foods were also similar in color and were from a narrow range or textures (crunchy or soft). He was also selective in terms of utensils, in that he would not take his formula feed from a cup or glass, although he would take water in this way.

Chris was also observed to exhibit ritualistic behavior around food, where he would require his caregiver at home or at school to touch each item of food before he would eat it. It seemed likely that Chris’s autism was contributing to a rigidity and fear of novelty, making it difficult to introduce new foods into his diet.

There were many components to Chris’s treatment. Initially, his nutritional needs were addressed by slowly fading out the infant formula diet and introducing a fortified milk shake. As he was overweight, Chris’s appetite was manipulated by restricting his access to his preferred food very gradually while carefully monitoring his weight. Chris was then slowly introduced to new food of a similar texture over a number of sessions, beginning with having food on the plate, progressing through to touching, licking, and tasting. Work was done with Chris’s family to ensure consistency at home and to manage parental anxiety.

There does not appear to have been much focus on the evaluation in 79 children with moderate-to-severe developmental disability and report that 56% demonstrated gastroesophageal reflux, and 27% had oropharyngeal dysphagia.

Feeding difficulties in children with autistic spectrum disorder (ASD) most commonly focus on selectivity by texture, taste, brand, presentation, or appearance, which may or may not result in failure to gain weight or weight loss. Technically without this, as mentioned earlier, such children do not fulfill existing diagnostic criteria for feeding disorder, despite presenting with significant feeding problems (see Vignette 1). Although a number of children with ASD will not fulfill formal diagnostic criteria for feeding disorder, they do commonly present to behavioral feeding clinics. Other problematic aspects at presentation in children with ASD include food refusal, failure to eat the usual family diet, inappropriate rate of eating, obsessive eating patterns, failure to accept novel foods, and inappropriate mealtime routines. These features at presentation may be a result of the attention to detail, perseveration, fear of novelty, sensory impairments, and biological food intolerances, which are all common in children with ASD. However, Schreck and Williams (2006) have challenged this view with the results of an informant-based questionnaire study, which surveyed parents of 138 children with ASD. Their findings revealed that the children were selective in the foods they accepted, but that this seemed to be more related to the family’s reported eating preferences than features of ASD per se. They conclude that their study found no evidence to support the commonly held view that typical features of autism, such as difficulty changing routines or sensory processing problems (e.g., difficulties with textures), are related to selectivity in feeding in this group.

The selective eating typically found in children with ASD can also be identified in children without diagnosed developmental disorder. Such children refuse to eat outside of a narrow range of preferred foods, and their feeding disturbance appears to be a highly circumscribed problem in a child who is otherwise developing and functioning within a normal range. These children often prefer carbohydrate-based food of bland flavors and colors and have a tendency to be more risk averse than may of their peers (see further Bryant-Waugh and Lask 2007, Nicholls et al. 2001). For a clinical example of food selectivity in the context of ASD, see Vignette 1.

Assessment

In the remainder of this section, discussion is not limited to feeding disorder, but includes the range of presentations of feeding problems seen in behavioral feeding clinic settings.

It is evident that comprehensive assessment is required in order to determine which of a range of potential factors may be relevant to the development and maintenance of a feeding problem in any one child. Effective feeding depends on the presence of required physical, social, and environmental factors. Assessment therefore needs to cover all these areas, to identify where difficulties might have existed or still exist that contribute to the feeding disorder. Table 47–2 gives the main areas usefully included in a comprehensive assessment. The specific nature and extent of the underlying features ascertained through assessment will help to guide treatment.

There does not appear to have been much focus on the development of standardized, validated assessment measures of feeding problems. Typically, centers seem to have developed their own assessment questionnaires (e.g., Douglas and Harris 2001, Harris and Booth 2006). One exception to this is Crist et al.’s Behavioral Pediatrics Feeding Assessment Scale (Crist et al. 1994, Crist and Napier-Phillips 2001). This is a 35-item questionnaire, which measures parent and child behaviors in the context of feeding problems in children aged 9 months to 7 years. Use of the scale generates four scores: child’s behavior—frequency, child’s behavior—problems, parents’ feelings/strategies—frequency, and parents’ feelings/strategies—problems. Psychometric properties for this scale are acceptable, with alphas for internal consistency for the behavioral items and the overall measure reported as 0.74–0.88 and test–retest coefficients between 0.82 and 0.85 (Crist et al. 1994). This measure has been used
The process of comprehensive assessment as outlined in Table 47–2 might highlight the need for further investigation before treatment can safely be commenced. For example, in a child with a history of chest infections, presenting with gagging and a refusal to swallow, a videofluoroscopy may be indicated. Such an investigation assesses oropharyngeal function and motility and can provide essential information for the treating team about whether it is safe to proceed with the promotion and encouragement of oral feeding.

In view of the diagnostic requirement for feeding disorder that there should be failure to gain weight or there should be an actual weight loss, a number of children may not get adequate access to assessment of clinically significant feeding problems. For example, children who are very selective about the range of foods they will eat may not exhibit weight or growth problems, as their overall energy intake may be satisfactory. Such children might then not be considered a priority for assessment and treatment despite often extremely poor nutritional status and behavior that represents a significant challenge to caregivers.

### Epidemiology

The overall estimates for prevalence of feeding disorder and feeding difficulties in children are very difficult to ascertain with any reliability. Researchers have tended to use different definitions, to have focused on specific subcategories of feeding disorders, or to have focused on children with particular disorders or syndromes. The prevalence rate of feeding disorders in the general pediatric population is reported as being about 25% (Babbitt et al. 1994), and although this general figure of one in four children in pediatric populations seems to be widely quoted, it is difficult to be entirely confident that this is accurate given the variability in use of the term feeding disorder. Rates are reported to be higher in children with developmental disability, with rates ranging up to 80% (Manikam and Perman 2000). Feeding difficulties, though not necessarily formal feeding disorder, are particularly common in children with pervasive developmental disorders. On reviewing the literature specifically in relation to children with ASD, Ledford and Gast (2006) report that up to 89% of children with ASD have problem feeding behaviors. Feeding problems are also common in children with neurological impairment (such as cerebral palsy, sensorineural deafness, and severe vision loss), with one study of 271 such children reporting 89% needing help with feeding, 56% experiencing choking episodes, 28% having feeding times of over 3 hours, and 20% having parents finding mealtimes to be stressful and not enjoyable (Sullivan et al. 2000). Other groups identified as particularly at risk include infants of premature birth, children with craniofacial anomalies, and those with certain genetic syndromes (such as Russell–Silver syndrome) (Lifschitz 2001). These studies combined suggest that problematic feeding behavior, which reaches clinical significance, is relatively common in a number of groups of children. This needs to be distinguished from any statements about rates of feeding disorder, as children with this diagnosis represent only a subset of children seen in feeding clinics.

### Comorbidity

Levels of comorbidity differ across the varying presentations of feeding problems. Timimi et al. report that in a cohort of 20 children presenting between 4 and 7 years of age with

by other authors (e.g., Burklow et al. 2002) and represents a useful tool for clinicians and researchers in this field.

Most clinicians regard direct observation of feeding behavior and interaction as an essential component of assessment (e.g., Babbitt et al. 1994, Chatoor et al. 2001). Observation of the feeding behavior allows visual assessment to be made of oral motor function, including chewing and swallowing ability, as well as assessment of sensory function and sensitivities. Direct observation typically involves the feeding dyad, that is, the caregiver and the child. However, Fosson and Wilson (1987) suggest that whole-family assessment is preferable. They report on the observational assessment of 34 families, with an infant diagnosed as having nonorganic failure to thrive. This study revealed that interactional factors often assumed to be contributing to the feeding problem, such as failure of the mother to respond appropriately to the infant’s cues, and apparent poor emotional attachment were observed in only 26% of the cases. They identified many other family interactional problems that appeared to be relevant to the feeding process, including sibling rivalry, displaced maternal anger, the mother being undermined, and chaotic family interactions. They conclude that observational assessment of early childhood feeding problems should include family assessment of functioning at mealtimes (Fosson and Wilson 1987).
extremely selective eating behaviors (95% of whom had onset of feeding difficulties before the age of 18 months), 30% had obsessions and compulsions and 40% had social and school attendance difficulties (Timimi et al. 1997). As previously mentioned, Axis II developmental disorders and Axis III physical conditions are common concomitants of an Axis I Feeding Disorder.

Course
Surprisingly little is known about the course and prognosis of feeding disorders in infancy and early childhood, and much useful work remains to be done in this area.

In a follow-up study of 24 children with early (aged between 3 and 12 months) refusal to eat with no apparent medical cause, compared to controls, children with early refusal to eat seemed to have an equally good general prognosis with respect to health, growth, and development at 4 years (Dahl and Sundelin 1992). However, although weight and height were within the normal range, less variability in weight and height was noted compared to controls. In addition, children with early refusal to eat were at increased risk of problems with their eating patterns and behavior, with 71% reported by their parents as still having minor feeding problems and 42% reported as being hyperactive (Dahl and Sundelin 1992).

An important and much quoted longitudinal study by Marchi and Cohen (1990) demonstrated an association between specific aspects of problematic infant feeding behavior (inadequate intake, choosiness, slow feeding, and lack of interest in food—all based on maternal report) and later development of symptoms of anorexia nervosa in adolescence. This research suggests that selectivity in early and middle childhood is predictive of elevated levels of symptoms of anorexia nervosa, but not bulimia nervosa in adolescence (Marchi and Cohen 1990).

In terms of the long-term implications of early feeding problems, the occurrence of disease in adults (including cardiovascular and respiratory disease) has been observed to be associated with low birth weight and with weight at 1 year (Barker 1994). One explanation is that nutritional deficiencies at critical points of development can lead to irreversible changes in physiological functioning (Barker et al. 1993), which highlights the long-term importance of maintaining adequate nutrition in childhood.

Differential Diagnosis
A diagnosis of feeding disorder of infancy or early childhood should be made only where there is significant weight loss or failure to gain weight. Where other medical conditions are directly and fully responsible for feeding impairment or weight loss, feeding disorder should not be diagnosed. Such conditions might include gastrointestinal, endocrine, or neurological conditions. However, as stated above, there is often an overlap between presenting features, with feeding disorder becoming appropriate as a diagnosis in situations where the level of disturbance is significantly greater than might be seen in other children with similar medical conditions or greater than predicted on the basis of the medical condition alone.

Because feeding disorders may be conceptualized as interactional disorders, a consideration of differential diagnoses must also include maternal or primary caregiver issues. For example, O’Brien et al. (2004) found relatively high rates of depression in mothers of infants presenting with poor weight gain. In some cases, treatment of the mother’s condition can result in improvement in the infant’s weight.

Etiology and Pathophysiology
Feeding disorders are generally regarded in most cases as multidetermined disorders. Conditions and factors implicated in etiology usually fall under three main headings: structural or oral, medical, behavioral, or psychosocial. Sometimes the treatment for an underlying medical condition can in itself contribute to the development or maintenance of a feeding problem. For example, a frequent complication of early tube feeding is that children go on to exhibit a resistance to oral feeding. This may stem from aversive experiences around the mouth, nose, and esophagus, such as intubation, which means that the child associates stimulation of this area with the previous traumatic experiences they have had (Benoit and Coolbear 1998) and hence will avoid it where possible. Children with early histories of inability to adequately feed orally, and who required tube feeding as neonates, represent a significant proportion of those presenting with feeding disorders and difficulties to specialist services.

Rommel et al. (2003) found a significant correlation between prematurity and feeding problems, which has been used to support the hypothesis that the origin of feeding disorders is more likely to be neurophysiologic than experiential or environmental (Ramsay et al. 1993). However, it is important to note that these premature babies are also likely to experience adverse experiences, such as ventilation and intubation, and can also spend time in incubators, which may lead to disrupted early attachments, which may in turn contribute to feeding problems (see Vignette 2 for an example of oral food aversion in a 5-year-old born prematurely).

There is a body of existing research examining whether and to what extent feeding disorders in children are related to parental characteristics and interactional processes between caregiver and child. Stein et al. (1995) compared 30 mothers of children with a feeding disorder with mothers of children with a behavioral disorder and with a community sample of mothers. Significantly higher rates of disturbed eating habits and attitudes were found in the mothers of children with feeding disorders, compared to the other groups. Such research is of interest in highlighting intergenerational aspects of feeding and eating problems, but it is not clear from this type of study whether the link between childhood feeding problems and maternal eating disturbance is primarily due to genetics or social learning.

Whelan and Cooper (2000) sought to confirm this link between childhood feeding problems and maternal eating disorder in a community study, which included filming family meals to achieve objective ratings of feeding problems. They found that mothers of children with feeding problems had markedly raised rates of past and current DSM-IV-TR eating disorder diagnoses, thus leading them to conclude that there is a strong and specific link between the two. This work was later extended to attempt to investigate mechanisms responsible for the relationship between reported feeding problems in childhood and eating disturbance in mothers in a further observational study (Cooper et al. 2004). They discovered two environmental variables—“mealtime disorganization” and “maternal strong control and disharmony”—as mediating the association between child and maternal disturbance.
Clinical Vignette 2

Case of Oral Food Aversion in a 5-Year-Old Boy Who Was Born Prematurely with Considerable Medical Problems

Andrew was born at 25 weeks weighing 650 grams at birth with a tracheoesophageal fistula. He was ventilated at birth. After his fistula repair Andrew was still unable to eat due to collapsed lungs. He remained in hospital for 6 months.

Andrew was bottle fed for about 1 week and was then fed by gastrostomy tube. His parents attempted forced feeding at 1 year and he began to show such strong oral aversion that he could not be kissed without gagging and retching.

Andrew had 19 dilatations of the esophagus before he was 3, where his very restricted esophagus would be manually stretched. Due to constant vomiting Andrew had a Nissens fundoplication at 1 year and remained on oxygen until he was 18 months. Andrew’s parents separated when he was 3.

Over the years Andrew has agreed to try small amounts of various foods; however, he will not swallow food and continues to require gastrostomy feeding, despite the fact that there is no longer any medical reason why Andrew cannot eat.

It is likely that the reasons for Andrew’s feeding difficulties are multifactorial. He had a number of very aversive invasive procedures around the mouth and esophagus, including ventilation and dilatations of the esophagus. He could not be fed orally at birth because of his fistula, which did not allow him to develop feeding skills in the normal way. Andrew’s parents’ separation may have introduced secondary gains for not eating, as they would unite to attend hospital appointments regarding his feeding.

Andrew’s long-term gastrostomy feeding means he did not get the opportunity to develop skills required for eating and he may have immature oral motor skills and a lack of pleasure in eating. He may also have no understanding of hunger, as all his nutritional requirements are met by the tube feeding. A period of forced feeding is likely to have compounded his oral food aversion.

Andrew’s treatment consisted of 12 fortnightly sessions lasting half a day and had many components, utilizing a multidisciplinary team. Because Andrew was very ill as a baby, his parents found it difficult to set firm boundaries. His parents were seen individually by a family therapist to work through these feelings and to educate them about strategies to improve Andrew’s feeding, such as graded exposure and basic behavioral principles. They were also supported by the therapist and the dietician to slowly reduce the volume of tube feeding to increase Andrew’s appetite. Some targeted work was done with Andrew around messy play and cooking by the team play specialist, to desensitize him to the touch and smell of food. He was rewarded using stickers and he learned to get pleasure out of food. Andrew and his family took part in group lunch sessions with the therapist, who modeled positive interactions around feeding. As Andrew had never been weaned, he was introduced to stage 1 purées, as his feeding skills were not consistent with his chronological age. Occasionally, his speech and language therapist attended to monitor his oro-motor skills and his swallow. There were firm expectations for Andrew to take gradual steps toward oral feeding. He was rewarded for his progress with praise and stickers.

Such studies have important implications for assessment and treatment of feeding disorders, underlining the importance of attending to contextual and environmental factors.

In another observational study of mother–child feeding interactions, Ammaniti et al. demonstrated an association between specific maternal characteristics (dysfunctional eating attitudes, anxiety, depression, and hostility), specific characteristics of the child (anxiety/depression, somatic complaints, and aggressive behavior), and dysfunctional interaction during feeding (Ammaniti et al. 2004). These authors conclude that their research supports the importance of assessing features specific to the child, features specific to the primary caregiver(s), and features of interaction around feeding to enable effective, targeted interventions.

Chatoor et al. have conducted many studies over a number of years aimed at better understanding the association between reciprocal relationship issues and feeding disorders (e.g., Chatoor et al. 1988). While it is acknowledged that feeding problems can and do arise in infants and young children with secure attachment relationships with caregivers, Chatoor et al. have proposed that insecure attachment relationships may intensify feeding problems and report an association between severity of attachment insecurity and severity of feeding disorder (Chatoor et al. 1998). An interesting study investigating touch patterns found that children aged 9–34 months with feeding disorders received less maternal affectionate and unintentional touch than the study controls (Feldman et al. 2004). The children with feeding disorders also displayed less affectionate touch, more negative touch, and were more rejecting of the mother’s touch. These authors conclude that proximity and touch between the caregiver and the child are disturbed in feeding disorders, suggesting fundamental problems in the relationship.

Lucarelli et al. (2003) compared mother–child interaction in children whose feeding disorder had an underlying organic cause, to those in whom there was no underlying medical condition, and found higher rates of dysfunctional interactions in both groups compared to controls. Such research raises the important question of whether it is the feeding disorder that contributes to the dysfunctional interaction or the interaction problems that maintain the feeding disorder.

There are relatively few studies investigating the role of fathers in young children’s problematic feeding and eating behaviors. One Finnish study aimed to investigate whether problem feeding behaviors at the age of 13 months and 5 years were associated with parental eating habits and attitudes, in a sample that included 375 fathers (Saarelaho et al. 2001). The authors found that the fathers’ difficulty in maintaining an ideal weight significantly predicted the persistence of problems at 5 years. They interpret their findings as suggesting that eating attitudes and behaviors of both parents are reflected in the feeding and eating behavior of young children. However, a recent review has concluded that there is as yet no consensus regarding the nature of the relationships between parent and child disturbance in relation to feeding and eating and that the mechanisms for inter-generational mechanisms remain to be firmly established (Coulthard et al. 2004).

Treatment

In practice most infants and young children with feeding disorders will be treated in a multidisciplinary team context,
which because of the complexity and multifaceted nature of these disorders is generally considered to contribute to better patient care. Multidisciplinary involvement in treatment is also considered essential, given the fact that the majority of feeding problems stem from an underlying medical and/or oral problem (Rommel et al. 2003). The mental health practitioner must therefore be aware of the role of other disciplines in treatment in this area, and in practice, many young children with feeding problems will receive collaborative input from a number of specialties.

Treatment Goals
The main aim of interventions designed for children with feeding disorders is to facilitate the establishment of nutritionally adequate oral feeding that is experienced positively. The detailed background to any one child’s feeding difficulties is likely to vary from that of another, as are the specific features at presentation. Treatment therefore ideally needs to be individualized to the child’s cognitive, psychological, and physical needs and context. A multicomponent approach to treatment including interventions targeted to the child, to the caregiver, to the interaction between the child and the caregiver(s), and to the broader environment is usually recommended (e.g., Davies et al. 2006). Table 47–3 summarizes the main treatment interventions offered to children with feeding disorders.

At present, treatment research in this area remains lacking, resulting in the evidence base for treatment of feeding disorders deriving mostly from clinical case series and expert consensus. There is a significant case report literature on therapeutic interventions on infants and children with feeding disorders, which have focused on stimulating the hunger–satiety cycle, reinstating hunger cues and feeding reflexes, improving oral motor skills, and improving caregiver’s attitudes, emotional state, and family functioning with varied outcomes. For a comprehensive account of treatment interventions for infants with feeding problems, see Wolke et al. (2006). For a useful, detailed description of the process of weaning children off gastrostomy tubes onto oral intake within a behavioral feeding program, see Byars et al. 2003.

The development of empirically validated treatment protocols specific to identified patterns of presentations could enhance the effectiveness of treatment of feeding disorders and is much needed. However, it could be argued that because the development and maintenance of feeding problems is so specific to any one individual, effective standardized treatment protocols will be difficult to achieve expect for highly circumscribed subgroups of children. Some authors have suggested that a way forward might be to conduct detailed functional analyses of feeding behavior, using a number of different procedures to clearly identify effective components of treatment (Najdowski et al. 2003).
